Abstract

In this experiment, we investigate real and simulated ATLAS data sets and determine the mass of the W boson. We do this by getting familiar with particle reactions at ATLAS using the ATLANTIS program. As a part of the assignment, we studied the `mystery-035-f.zip` data set and `ATLASData-Cosmics-M5.zip` data set. After that, we applied calibration to the raw data using the Z^0 peak. The calibrated data gave a peak at 91.198 ± 0.0196 GeV, which corresponds to the mass of Z^0 boson, and we obtain a resolution of 2.342 ± 0.024 . After applying the calibration to the data, we determined the W boson mass by observing the position of Jacobi peak. We set the QCD background scaling factor to 0.3 and applied cuts of `el_etiso < 8` GeV and `njet = 0`. Further, we considered uncertainties arising due to systematic errors. Using the gauge curve with half-maximum points from simulated data sets, we obtained a mass of 80.45 ± 0.10 (stat.) $- 0.22^{+0.02}_{-0.03} {}^{+0.10}_{-0.18}$ (sys.) GeV from real ATLAS data, which is 0.18σ away from the literature value. Similarly, we determine the mass of Z^0 and we obtain a value of 90.94 ± 0.20 (stat.) $- 0.25 {}^{+0.02}_{-0.02} {}^{-0.46}$ (sys.) GeV. This value is 1.26σ away from the literature value. The cause for these deviations is attributed to noisy data in the peak region and statistical fluctuations. However, when considering systematic uncertainties we observe that varying the fit region and the calibration also strongly affected the deviation.

Chapter 1

Introduction

In this laboratory experiment, we are introduced to the physics of the Large Hadron Collider (LHC). At LHC, proton beams are collided at a center-of-mass energy of 14 TeV. Such high energies allow us to probe the structure of fundamental particles and study their interactions with high precision. Studying physics at this scale allows us to answer bigger questions, about cosmology, what our universe is composed of and what happened in the events that followed the Big Bang. Further, it could hold answers to physics that has never been observed before, which would further our understanding of the universe. This search for answers pushed physicists around the world to build bigger colliders that could reach higher energies. And with each of these came the discoveries of fundamental particles, with the last of them being the Higgs Boson, discovered in the year 2012.

In this experiment, we start off by getting familiar with ATLANTIS, a program that displays particle reactions graphically. Using ATLANTIS we explored several data sets and got familiar with different kinds of decay channels at LHC. As a part of assignment, we analyzed two different data sets in particular. This is followed by calibration of the raw data, which is done by calibrating the invariant mass distribution of electron positron pair to a well-known Standard Model (SM) parameter, the mass of Z^0 boson. After applying the calibration to the data, we measure the mass of the W boson. This is done by observing the position of the Jacobi peak from the electron p_T distribution resulting from $W \rightarrow e\nu$ events. We apply the gauge curve to real ATLAS data to determine the mass of Z^0 boson to cross check our results. Lastly, we consider systematic errors that arise during the measurements.

In Chapter 2, we briefly go through the important theory behind the SM and the ATLAS detector. In Chapter 3, we provide solutions to the pre-lab questions from the laboratory manual. In Chapter 4, we use the ATLANTIS program to look at the particle reactions of several data set. Further, we analyze the `mystery-035-f.zip` data set and `ATLASData-Cosmics-M5.zip` data set. In Chapter 5, we use the well-known parameter of SM, the Z^0 mass in order to calibrate our data. This is done by tweaking the energy scaling of different parameters in different regions of its spectrum. In Chapter 6, we use the Jacobi peak to determine the mass of W boson. Further, using simulated data, which considers different masses of W boson, we obtain the parameters for gauge curve, which allows us to obtain the W mass. We cross verify this result by using the curve to determine the mass of Z^0 boson. In Appendix A, we include additional figures for the sake of completeness. In Appendix B, we include the code used for calibration of electrons and macro file used for obtaining half-maximum for each simulated plot. This report closely follows the student lab manual from [1]. All the constants for SM particles were obtained from [2]. All units are in natural units, i.e., $c = \hbar = 1$.

Chapter 2

Theory

2.1 The Standard Model

The Standard Model (SM) is one of the most tested theories in physics. It classifies all the known elementary particles into fermions and bosons and describes three of the four known fundamental forces of nature, strong, weak and electromagnetic force [2]. It is a gauge quantum field theory which contains the internal symmetries of the product group, $SU(3) \times SU(2) \times U(1)$. The fermions are spin-1/2 particles and are further classified into quarks and leptons, each with three generations. The bosons are categorized by their spin with gluons, photons, Z^0 and W^\pm boson having spin 1 and the Higgs boson with spin 0. Apart from the gluons and photons, the other bosons are massive. The elementary particles of the SM are shown in Fig. 2.1.1.

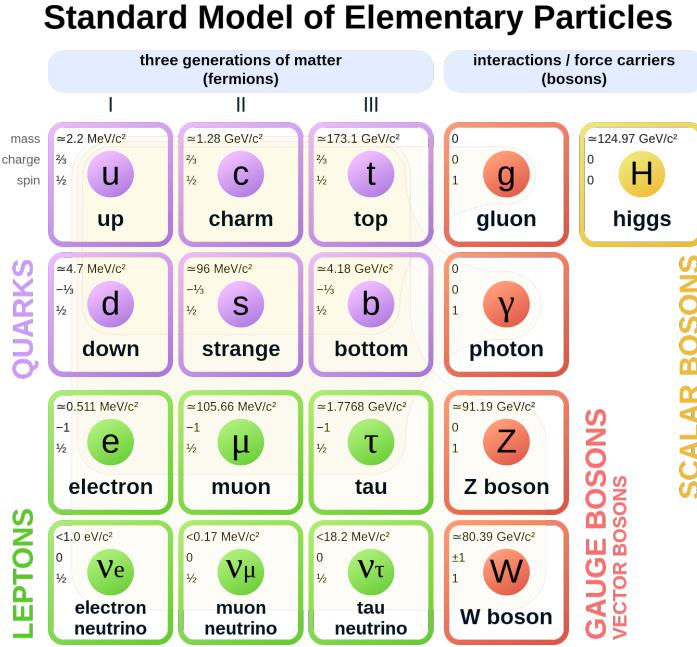

Figure 2.1.1: The Standard Model particles [3].

Despite its huge success, the SM fails at several fronts. It fails to explain matter-antimatter discrepancy, neutrino oscillations, dark matter and hierarchy problem to name a few. In order to test the SM and build a better theoretical framework that tries to answer all of the issues with SM, the Large Hadron Collider (LHC) was built between 1998 and 2008.

2.2 LHC and the ATLAS Experiment

2.2.1 Large Hadron Collider

The Large Hadron Collider (LHC) is a circular particle accelerator for proton-proton collisions, located at the European Organization for Nuclear Research (CERN) at Geneva, Switzerland. Within the accelerator, two proton beams, accelerated and guided by superconducting cavities and electromagnets respectively, traverse in opposite directions propagating close to the speed of light. These beams then collide at four different interaction points with a center-of-mass energy of up to $E_{CM} = 14 \text{ TeV}$, corresponding to the following experiments: ALICE, LHCb, CMS, and ATLAS.

In our laboratory experiment, we work with the simulated and real data obtained from the ATLAS detector from proton-proton collisions at center-of-mass energies at 14 TeV, and as such we will focus on the ATLAS detector in this report.

2.2.2 The ATLAS Detector

The ATLAS detector (**A** Toroidal **L**H**C** Apparatu**S**) is the largest detector placed at the LHC. It is 46m long, 25m high, and weighs approximately 7000 tons. The massive size of the detector allows coverage of almost all solid angles. The ATLAS detector is a multi-layered structure, consisting of different detector components constructed to detect the many different particles that emerge from the final products of the collision. See Fig. 2.2.1 for a schematic of the ATLAS detector. The detector components can largely be divided into three regions: the Inner Detector, Calorimeter, and the Muon System.

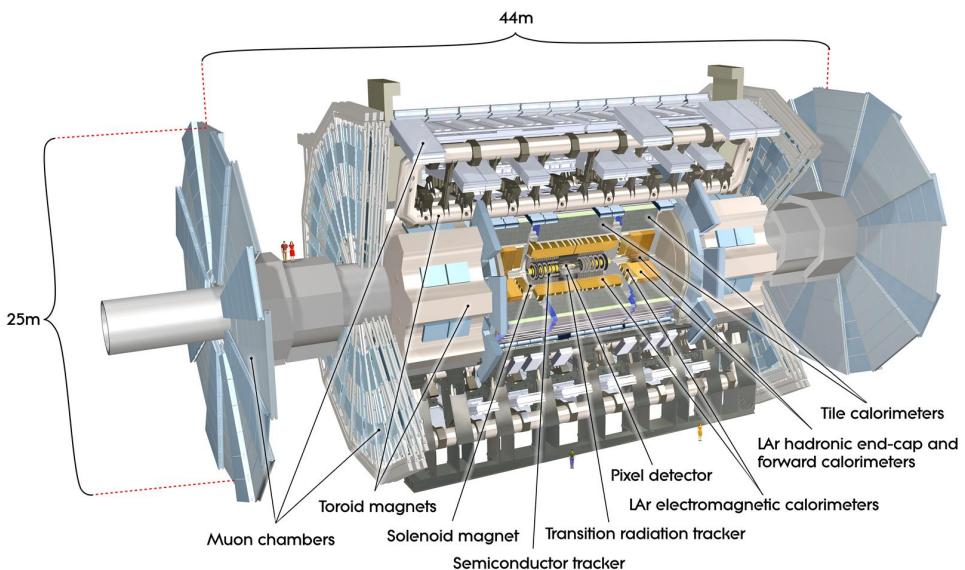

Figure 2.2.1: The schematic of the ATLAS detector. Obtained from Ref. [4].

(a) Inner Detector

The inner detector is the closest detector from the interaction point. To properly reconstruct the primary vertex, the detectors in this region are very sensitive. The inner detector, along with the solenoid surrounding it, allows measurements of the direction, momentum, and electrical charge of the produced particles in the proton-proton collision. The inner detector can subsequently be separated into four parts.

Pixel Detector

The pixel detector is located most closest to the interaction point with a radial distance of 5 – 15cm to the proton beam. The detector processes signals of over 80 million pixels, thus having the most readout channels out of all the detector components. This allows sensitive measurements on the charged particle

trajectory (hits) as well as reconstruction of the primary vertex. It also helps in reconstruction of secondary trajectories, which occur in decay of b-quark hadrons.

Semi-Conductor Tracker (SCT)

This component is placed in between the pixel detector and the Transition Radiation Tracker (TRT). It operates similarly to the pixel detector, but silicon strips with length 80 μm are used instead of pixels. These silicon strips allow measurements of the position of the charged particles to an accuracy of 17 μm per layer. The area is also much larger than the pixel detector, making it an important component of the inner detector [4].

Transition Radiation Tracker (TRT)

This component is placed at the outermost part of the inner detector. This detector consists of both a straw tracker and a transition radiation detector. The noble gas contained within each straw ionizes and produces a signal in the wire when a charged particle passes through it. The signal is further enhanced by transition radiations that occur due to the materials contained between the straws. This tracker helps to distinguish the type of charged particle that flew into the detector, for example whether if it is an electron or a pion [4].

Solenoid

The inner solenoid is a superconducting magnet surrounding the inner detector. It provides the inner detector with a solenoidal magnetic field strength of 2 T, allowing the charged particles to bend due to the Lorentz force. This allows one to distinguish the electric charge of the particle as well as measure the momentum p through the radius of curvature of the particle. This can be shown by equating the Lorentz force to the centripetal force:

$$|\vec{F}_L| = |\vec{F}_C| \implies evB = \frac{mv^2}{R} \implies R = \frac{mv}{eB} = \frac{p}{eB} \quad (2.2.1)$$

where $\vec{v} \perp \vec{B}$ from the detector geometry. We further observe that positively and negatively charged particles will have opposite radius of curvatures. As neutral particles such as photons or neutrons have no electric charge, they show no curvature when they traverse through the inner detector.

(b) Calorimeter

The calorimeter, placed outside the solenoid, measures the total energy of the particles. These particles are often entirely stopped within the calorimeter, forcing all of their energies to be deposited in the detector. There are two types of calorimeters used.

Presampler

Before the calorimeters, a presampler is placed to support measurement of electromagnetic showers. Specifically, it helps to distinguish between single photons and photons from π^0 decays.

Electromagnetic Calorimeter (ECAL)

The electromagnetic calorimeter (ECAL) absorbs the energies of particles that interact electromagnetically, that is, those with an electric charge as well as the photon. It consists of alternating layers of iron and liquid argon, acting as the absorber and the ionization chamber respectively. The ECAL is folded similarly to an accordion such that it has an angle of 45° with respect to the charged particle trajectories.

In the ECAL, electromagnetic showers, that is, a cascade of interactions between photons, electrons, and positrons, are produced and measured. At the relevant energy regime, photons and electrons (and positrons) interact with matter most commonly via Compton scattering, pair production, or bremsstrahlung. These three interactions occur interchangeably, producing subsequent electrons and photons. This leads to a cascade of such particles, which is known as an electromagnetic shower. The number of particles produced in this shower is proportional to the primary energy. The longitudinal

extension is described by its radiation length X_0 , defined such that after one radiation length an electron only retains $1/e$ of its initial energy. These radiation lengths in solids are typically of order cm.

As muons have a higher mass, they do not undergo bremsstrahlung and as such not detected in the ECAL¹. As such, a separate system is constructed to detect muons, which will be mentioned in the subsequent subsection.

Hadronic Calorimeter (HCAL)

The hadronic calorimeter (HCAL) are used to produce and detect hadronic showers, that is, cascades produced by hadrons (mostly pions and kaons). The HCAL operates in a similar fashion to the ECAL, however, the size of the HCAL is much larger, ensuring that the hadrons are absorbed completely. The shower layers consist of iron, and to detect such particles liquid-argon chambers and scintillation tiles are used.

The hadronic showers generated in the HCAL are produced by inelastic interaction between the hadron and the nuclei in the material. These hadrons interact strongly, producing numerous hadrons and nuclei remnants, producing subsequent hadrons. This causes an avalanche of reactions, constructing a hadronic shower. Similar to electromagnetic showers, the longitudinal extension of the hadronic shower is estimated by its hadronic interaction length λ . The interaction length is defined such that after one interaction length, the number of hadrons that did not yet take part in the strong interaction decreases to $1/e$. The interaction length is often much larger than the radiation length.

(c) The Muon System

As previously mentioned, muons do not emit bremsstrahlung and thus are not absorbed by the ECAL. Thus a separate system is necessary to measure the muon trajectory and momentum. In the muon system, tracking chambers that fill up to half of the detector's volume is placed outside the calorimeters. The number of hits are then measured, allowing for measurements in the muon's position. Furthermore, large superconducting toroids are placed outside the tracking chambers with a magnetic field strength of 4 T, allowing measurements of the muon's momentum as well.

2.2.3 Interaction of Particles in Detectors

As mentioned in the previous section, different detector components allows measurements of different type of particles. In this section, we highlight the signature of each particle in the detector. Fig. 2.2.2 shows a schematic of all such signatures.

Electrons and Positrons

Electrons and positrons are mostly highly relativistic due to its smaller mass. They are electrically charged and thus bend when hits are measured in the inner detector. As they undergo bremsstrahlung and Compton scattering, they are readily absorbed in the ECAL, generating an electromagnetic cascade.

Photons

Photons are electrically neutral and are highly energetic with energies $> 1 \text{ GeV}$, so they do not show any hits in the inner detector. However, they undergo pair production and Compton scattering and are thus absorbed in the ECAL. Thus photons also produce an electromagnetic cascade.

Hadrons

Hadrons which are electrically charged ($\pi^\pm, K^\pm, p, \bar{p}$ etc) bend when their hits are observed as with e^-, e^+ , but do not leave any signature in the ECAL as they are much heavier than electrons and positrons. They are, however, absorbed in the HCAL, producing a hadronic cascade.

Hadrons which are electrically neutral, such as neutrons do not leave any hits in the inner detector nor do they produce any electromagnetic cascades. As they interact strongly, they produce hadronic

¹Muons with energies TeV or higher do lose their energy via bremsstrahlung significantly and show signature in the ECAL before leaving the detector.

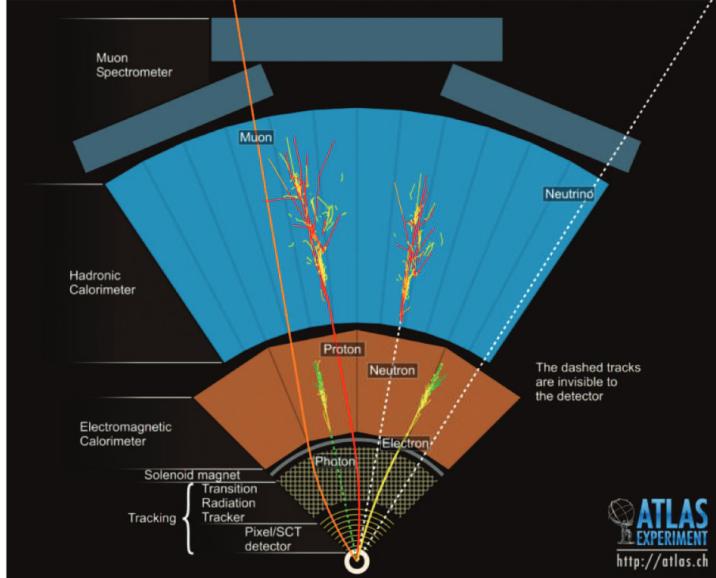

Figure 2.2.2: Signatures of different particles observed in the ATLAS detector. The electromagnetic and hadronic cascades can be seen from the ECAL and HCAL respectively. Obtained from Ref. [5].

cascades in the HCAL, making the curvature in the trajectories the only way to distinguish between electrically charged and neutral hadrons. Neutral pions are an exception to this as they primarily decay into photon pairs, which are subsequently observed in the ECAL.

Hadrons containing b quarks have an extremely long lifetime as the b quark itself has a long lifetime. They most often decay inside the beam pipe, located outside the detector system itself. As the decay vertex is far away enough from the primary vertex, suitable reconstruction methods can be used to identify the B hadrons. This is done by b-jet tagging, where the innermost detector is used to identify the jets from the b quarks.

Muons

Muons are charged leptons and thus their trajectories bend in the inner detector. Due to their high mass, however, they do not emit bremsstrahlung and thus do not leave any signature in both ECAL and HCAL. They are separately measured by the tracking detectors placed outside the calorimeters, where the curvature of the trajectory can be observed due to additional magnetic field placed.

Tau

Tau leptons (τ^\pm) are much heavier than muons ($m_\tau \approx 1 \text{ GeV}$) and their range in matter is limited to millimeters as they have a short lifetime. They most commonly decay weakly into hadrons ($\tau^- \rightarrow \text{hadrons} + \nu_\tau$), which can be identified in the detector as collimated “mini jets”.

Top Quark

The top quark is the only quark which decays before it can form jets due to its heavy mass of approximately 170 GeV. They primarily decay weakly via $t \rightarrow W^+ b$, i.e. to a b-quark. The top quarks can be identified by the decay products of the W boson and the jets from the b-quark, i.e. with three jets or jets with a $l\nu_l$ pair.

Neutrinos

Neutrinos only interact weakly and thus direct detection of single neutrinos within this detector is not possible. However, neutrinos with a high enough transverse momentum are detected indirectly by using conservation laws. This will be further elaborated in Sec. 2.3.

2.2.4 Coordinate System

In Cartesian coordinates, we set the axes such that the origin is placed at the collision point. The z axis is defined to be aligned with the beam axis. The x axis is defined such that it points towards the center of the LHC ring. The y axis is defined to be perpendicular to the beam axis.

From this, we can define relevant quantities that are frequently used to describe the detector coordinates:

- Radial distance to z -axis $\rho = \sqrt{x^2 + y^2}$
- Azimuthal angle ϕ , defined from the x -axis
- Polar angle θ . The angle is defined such that $\theta = 0$ is aligned with the xz -plane and $\theta = \pi/2$ is aligned with the y -axis.

A schematic of the coordinate system with the above relevant quantities is shown in Fig. 2.2.3.

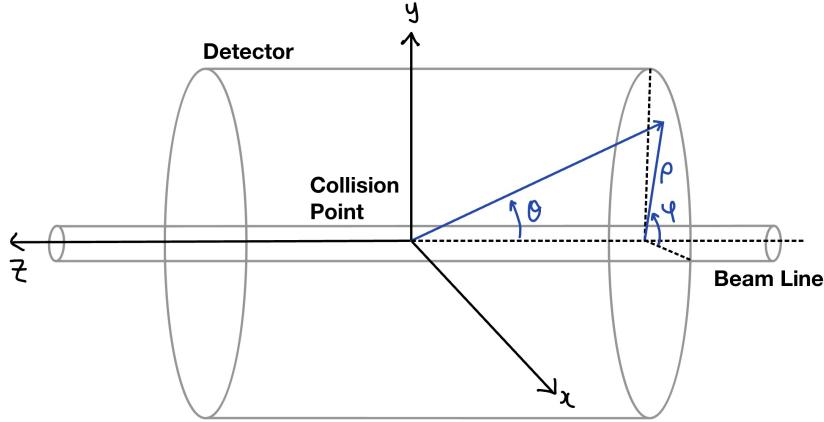

Figure 2.2.3: Schematic of the coordinate system defined for the ATLAS detector. The radial distance to the z -axis ρ , azimuthal angle ϕ and polar angle θ is also shown. Image based on Ref. [6].

We also define the pseudorapidity η as such:

$$\eta = -\ln \tan\left(\frac{\theta}{2}\right) \quad (2.2.2)$$

where θ is the polar angle. The pseudorapidity is defined such that $\eta = \pm\infty$ is defined in the direction of the $\pm\hat{z}$ axis respectively. Fig. 2.2.4 shows how the pseudorapidity and polar angle are related. The ATLAS detector detects leptons in $|\eta| < 2.5$ and jets in $|\eta| < 5$. Using the pseudorapidity is especially useful for the ATLAS experiment as the final products from proton-proton collisions increases strongly in the forward direction (near the beam axis).

2.3 The Heavy Gauge Bosons

The W^\pm and Z^0 are massive bosons which are responsible for the weak forces. The electromagnetic and the weak interactions are unified in the SM to give the electroweak force. The electromagnetic force arises due to $U(1)_Y$ (Y is hypercharge) gauge symmetry and the weak force arises due to $SU(2)_L$ (L is left-handed chiral) gauge symmetry. After Spontaneous Symmetry Breaking (SSB), the W^\pm and Z gain mass while the photon continues to be massless. In this experiment, our aim to is learn the methods of measuring the mass of the W boson. Some important vertices of weak interaction are shown in Fig. 2.3.1.

The mass of the Z^0 boson has been measured with high precision at the LEP accelerator in the year 2006 [8]. Its mass was found to be 91.1876 ± 0.0021 GeV. Since the Z^0 boson decaying to leptons (as shown in Fig. 2.3.1a) gives the cleanest signal to reconstruct its invariant mass, these events are usually studied. However, in the case of W boson, which decay to $W \rightarrow e\nu_e$ or $W \rightarrow \mu\nu_\mu$, the invariant cannot be reconstructed directly. This is because neutrinos interact weakly and are not detected. This makes

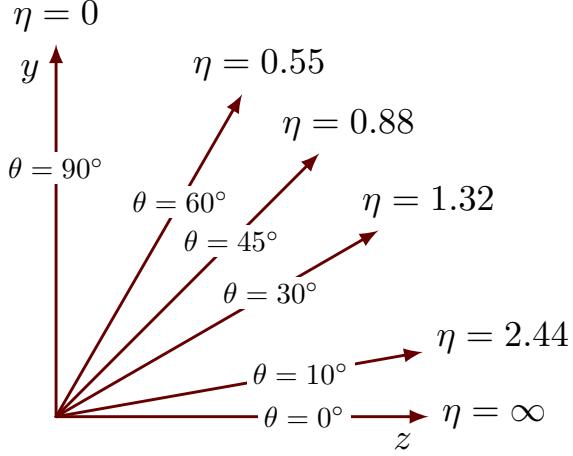

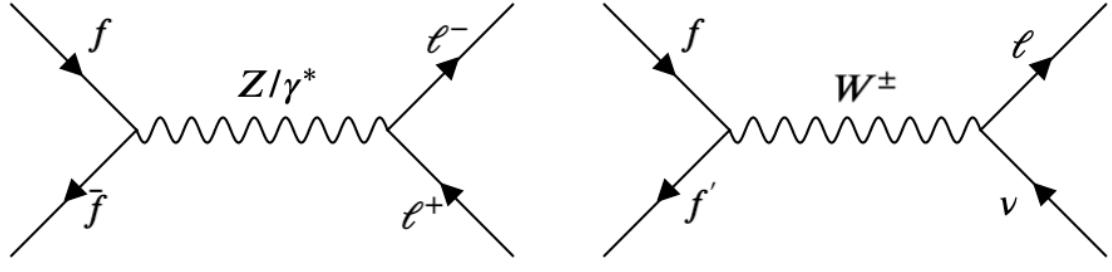

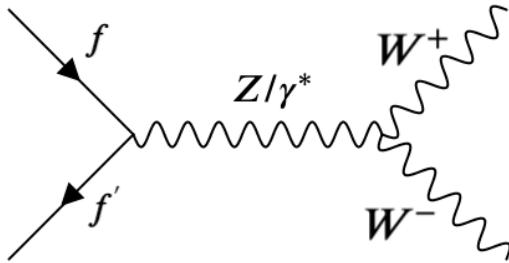

Figure 2.2.4: The pseudorapidity and its relation to the polar angle. The values from the y-axis to the $+z$ -axis is shown. Obtained from Ref. [7].

(a) Fermion anti-fermion going to Z^0 boson or a virtual photon to give lepton anti-lepton pair.

(b) Fermion anti-fermion going to W^\pm to give lepton (anti-lepton) and anti-neutrino (neutrino). This process is the weak Drell-Yan process.

(c) Fermion anti-fermion going to Z^0 boson or a virtual photon to give W^\pm pair.

Figure 2.3.1: Important weak interactions at LHC. Here f stands for fermion and l for leptons.

measuring the mass of the W boson a challenge and it is also one of the less known parameters of the SM. As of writing this report, a high precision measurement by the CDF collaboration of W boson mass was made in April, giving a value of 80.433 ± 0.009 GeV [9]. This result has a 7σ deviation from the SM prediction, suggesting inaccuracies in the calculations or possibility of new physics. Before this, the most precise measurement was made in 2018 and found to be 80.379 ± 0.012 GeV [10].

There are two notable ways to measure the mass of the W boson. The first utilizes the variable M_T , which is defined as

$$M_T = \sqrt{2p_{T_e} p_{T_\nu} (1 - \cos(\phi_e - \phi_\nu))}, \quad (2.3.1)$$

where p_{T_e} and p_{T_ν} are the transverse momentum of the electron and neutrino respectively, ϕ_e and ϕ_ν are the azimuthal angles. If we consider the mass of the electron to be zero, M_T is equal to W mass. The distribution of M_T gives us a Jacobi peak at the W mass. The advantage of using this method is that the transverse of momentum of the W boson does not significantly affect the position of the peak. The disadvantage is the use of p_{T_ν} , which as mentioned before, cannot be measured directly. Hence, it must be approximated using \cancel{E}_T , which is missing transverse momentum, given by

$$\cancel{E}_T = - \sum_i E^i \sin \theta_i \vec{n}_{i,\perp}, \quad (2.3.2)$$

where E^i is the energy of the i -th entry in the calorimeter, θ_i is the polar angle of the entry and $\vec{n}_{i,\perp}$ is the unit vector pointing towards energy entry in the x-y plane. Which means, that in order to measure M_T accurately, \cancel{E}_T has to be well calibrated.

The second method to measure the W mass is by studying the transverse momentum spectrum of the leptons using

$$\frac{d\sigma}{dp_T} = \frac{d\sigma}{d \cos \theta^*} \left| \frac{dp_T}{d \cos \theta^*} \right|^{-1} = \frac{d\sigma}{d \cos \theta^*} \frac{2p_T}{M_W} \frac{1}{\sqrt{1/4 M_W^2 - p_T^2}}. \quad (2.3.3)$$

This gives a Jacobi peak as shown in Fig. 2.3.2. The peak is at half of W mass, therefore, one can measure this peak in order to deduce the W mass. However, the figure shows the ideal case, in which the W boson does not have an initial transverse momentum. As shown in the same figure, if W has an initial momentum, there is a spread in the distribution and a shift in the Jacobi peak. Other factors that can increase the spread are the resolution of the detector and W -decay width. However, the advantage of using this method is that it does not require the complicated calibration of \cancel{E}_T . In this experiment we use this method. An interesting side note, the recent high precision measurement from 2022 used the first method to measure the W mass [9].

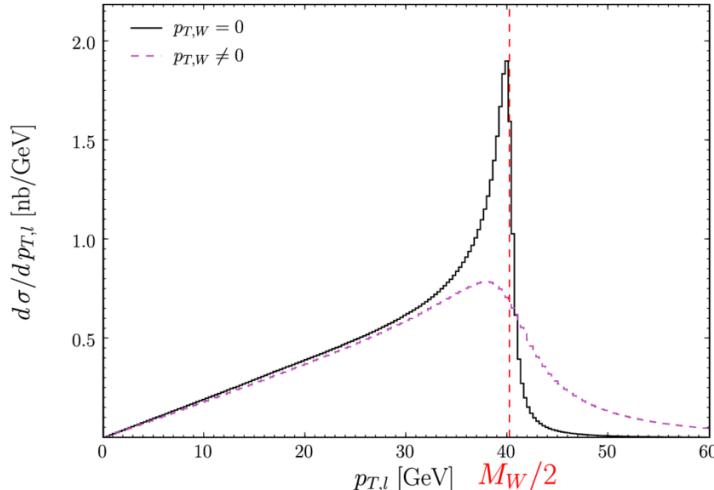

Figure 2.3.2: p_T spectrum of leptons from the $W \rightarrow l\nu$ decay. We see a Jacobi peak at half the mass of W boson [11].

Chapter 3

Pre-lab Questions

3.1 Part 2: Calibration of Electrons

1. Which value does the momentum of an electron have in the decay of a Z^0 boson $Z^0 \rightarrow e^+ + e^-$, if the Z^0 is at rest?

Solution:

Given that the Z^0 boson is at rest, $\vec{p}_Z = 0 \implies E_Z^2 = \vec{p}_Z^2 + m_Z^2 = m_Z^2$ so that $E_Z = m_Z$. This implies that the 4-momentum of the Z^0 -boson is $p_Z = (m_Z, \vec{0})$. Now by conservation of 4-momentum, we know that $p_Z = p_{e^+} + p_{e^-} \implies p_{e^+} = p_Z - p_{e^-}$.

Now taking the dot product of p_{e^+} , we have that:

$$\begin{aligned} p_{e^+} \cdot p_{e^+} &= m_e^2 = (p_Z - p_{e^-}) \cdot (p_Z - p_{e^-}) = m_Z^2 + m_e^2 - 2p_Z \cdot p_{e^-} = m_Z^2 + m_e^2 - 2m_Z E_e \\ &\implies m_Z = 2E_e \Rightarrow E_e = \frac{m_Z}{2} \end{aligned}$$

where the property $(p \cdot p) = E^2 - \vec{p}^2 = m^2$ was used.

To then determine the momentum of the electron, we use the energy-momentum relation again:

$$\begin{aligned} E_e^2 = \vec{p}_e^2 + m_e^2 &\implies |\vec{p}_e| = \sqrt{E_e^2 - m_e^2} = \sqrt{\left(\frac{m_Z}{2}\right)^2 - m_e^2} \\ &\implies |\vec{p}_e| = \sqrt{\left(\frac{91.18\text{GeV}}{2}\right)^2 - (5.11 \times 10^{-4}\text{GeV})^2} \approx 45.59\text{GeV} \end{aligned}$$

where the mass of the electron was neglected.

Thus the momentum of the electron from a Z^0 boson decay at rest is $|\vec{p}_e| = 45.59\text{GeV}$.

2. How large is the momentum of tau leptons in the reaction $e^+ + e^- \rightarrow \tau^+ + \tau^-$, if the reaction takes place in the center-of-mass system (center-of-mass energy = 5 GeV)?

Solution:

We know that the mass of the tau lepton is $m_\tau = 1.776$ GeV. Given that the CoM energy is $\sqrt{s} = 5$ GeV, by conservation of energy we have that:

$$\begin{aligned} s = (2E_e)^2 &= (2E_\tau)^2 = 4(\vec{p}_\tau^2 + m_\tau^2) \implies |\vec{p}_\tau| = \sqrt{\frac{s}{4} - m_\tau^2} \\ &\implies |\vec{p}_\tau| = \sqrt{\frac{(5\text{GeV})^2}{4} - (1.776\text{GeV})^2} = 1.7595\text{GeV} \end{aligned}$$

3.2 Part 3.1: W-Boson Measurement

1. As before, the analysis is based on ROOT trees. One of the tree variables is `ptw` - the estimated transverse momentum of the W boson candidate. This variable can be constructed from the other tree variables. Please think about how this could be done. The tree variables are listed in section B.

Solution:

Given that the weak interaction is described by $W \rightarrow l + \bar{\nu}_l$, we can calculate the transverse momentum of the W boson from the transverse momentum of l and $\bar{\nu}_l$. The formula to evaluate this is:

$$p_{T_W} = \sqrt{p_{T_l}^2 + p_{T_{\bar{\nu}}}^2}$$

which is derived from the conservation of 3-momentum.

This is defined in ROOT as `e1.pt` and `etmis`, so that the transverse momentum of the W boson candidate can be calculated as such: $\sqrt{\text{e1.pt}^2 + \text{etmis}^2}$.

2. When fitting measurements to a linear function, the two parameters of a best fit straight line are y-intercept and slope. The errors on these parameters are typically correlated. Using these parameters for the error analysis will require a treatment that takes correlations into account. For example the simplest form of Gauss' error propagation law requires that the errors are uncorrelated. Please look up the correct form of the Gauss error propagation law in the presence of correlations. You will need that for the final error on the W mass. On the other hand, is it possible to minimize correlations by choosing an appropriate coordinate system?

Solution:

The Gauss error propagation law in the presence of correlations is given as such:

$$\sigma_f^2 = \left(\frac{df}{dx}\right)^2 \sigma_x^2 + \left(\frac{df}{dy}\right)^2 \sigma_y^2 + 2 \left(\frac{df}{dx}\right) \left(\frac{df}{dy}\right) \rho_{xy} \sigma_x \sigma_y$$

where ρ_{xy} is the correlation coefficient which yields zero for uncorrelated errors. The correlation matrix is then defined with the variance σ_x^2, σ_y^2 in its diagonals with the correlations $\rho_{xy} \sigma_x \sigma_y$ in the off-diagonal components.

To minimize correlations, we can convert to an appropriate coordinate system in which the correlation matrix becomes diagonal. This will allow the cross terms to vanish.

3.3 Part 3.2: New Physics

1. What is the minimum invariant 4-lepton-mass, when the four leptons originate from a Z^0 pair? Why do you find 4-lepton-events with invariant mass beneath this threshold?

Solution:

In theory, the minimum invariant mass of each lepton should be $m_Z/2$. In addition to the lowest order Feynman diagrams, there are two higher order diagrams where the photon is radiated by initial-state quarks, called Initial State Radiation (ISR), due to which there is a shift in the energy of the ingoing particles, leading to a distortion in the shape of the Z resonance curve. Therefore, the effect of ISR is to reduce the effective centre-of-mass energy of the ingoing particles, which leads to some fraction of Z^0 boson invariant mass to be beneath this threshold. Another possible reason can be that in the case of more than one Z^0 boson, the other Z^0 boson will not be on-shell due to kinematic reasons. Due to this, we get one Z^0 boson and another virtual Z^* boson. Hence, the mass of the 4 leptons, would be below the threshold.

2. Consider a Higgs boson which decays into two Z^0 bosons. How does the distribution of the 4-lepton-invariant-mass look like?

Solution:

The distribution will follow a Voigt function peaked at 125 GeV (Fig. 3.3.1).

3. Assume you have an ideal detector. What is the typical \cancel{E}_T if a Z^0 pair has been produced and both Z^0 decay into electron or muon pairs? What \cancel{E}_T will you expect when you have a real detector?

Solution:

In an ideal case, the expected \cancel{E}_T is 0. In the case of real detector, \cancel{E}_T will be non-zero due to inefficiencies in the detector and reconstruction algorithms. Further, not all muons and electrons will be detected. Or, one of the leptons could be extremely soft and not be detected at all.

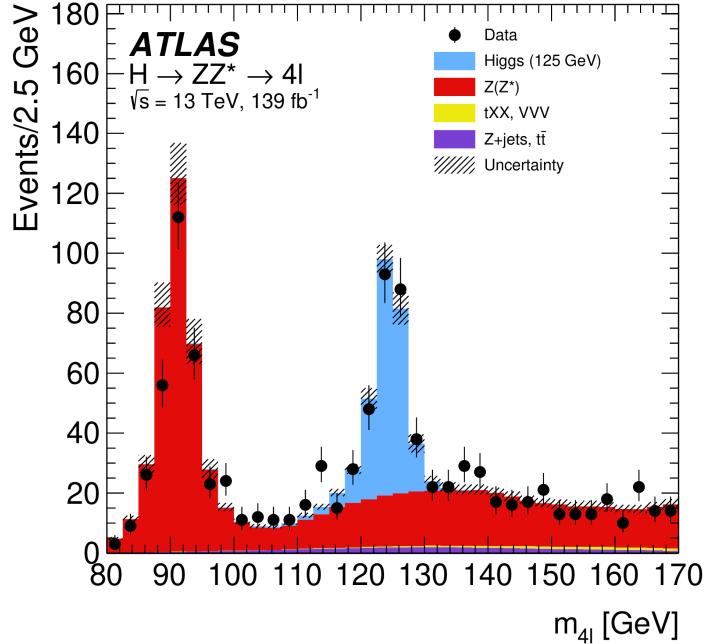

Figure 3.3.1: ATLAS four lepton invariant mass measurement showing evidence for the Higgs boson [12].

4. The Branching ratio of $t \rightarrow Wb$ is almost 100%. If you have a top anti-top pair in an event, both particles decay instantly via $t \rightarrow Wb$. If both W bosons each decay leptonically ($W \rightarrow l\nu$), one finds two leptons in the event. What could explain the occurrence of four leptons in a $t\bar{t}$ event?

Solution:

- One of the leptons radiates a photon/Z* boson which gives lepton-antilepton pair, $l \rightarrow l + \gamma \rightarrow l + l^+ + l^-$.
- b-quark can decay semi-leptonically, giving us hadrons plus a lepton (Fig. 3.3.2).

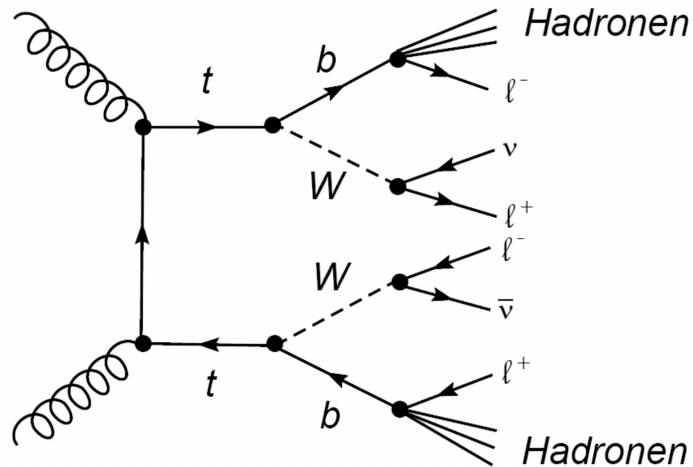

Figure 3.3.2: Top and b-quark decay process [1].

Chapter 4

ATLANTIS

In this part of the lab, we get familiar with the program ATLANTIS, which displays particle reactions in the ATLAS detector graphically. From this program, one can easily retrieve relevant quantities such as the particle's transverse momentum, azimuthal angle and pseudorapidity from the given datasets. Before looking at the assignments for this part, we first become acquainted with all the data sets. We present our observations below.

4.1 Electron Dataset

In this dataset, we observe the signature of a single electron in the detector. Fig. 4.1.1 shows the output from ATLANTIS for Event 7 in the dataset. In each figure shown in this section, the upper left figure shows the xy projection of the event. The upper right top shows a zoomed-in xy projection at the inner detector. The upper right lower figure shows the ρz projection, and the lower figure again shows the zoomed-in ρz projection at the inner detector and calorimeters. The blue line are the reconstructed tracks and the yellow boxes are the energy depositions in the calorimeters. Finally, the red dashed line indicates the E_T obtained from kinematical calculations.

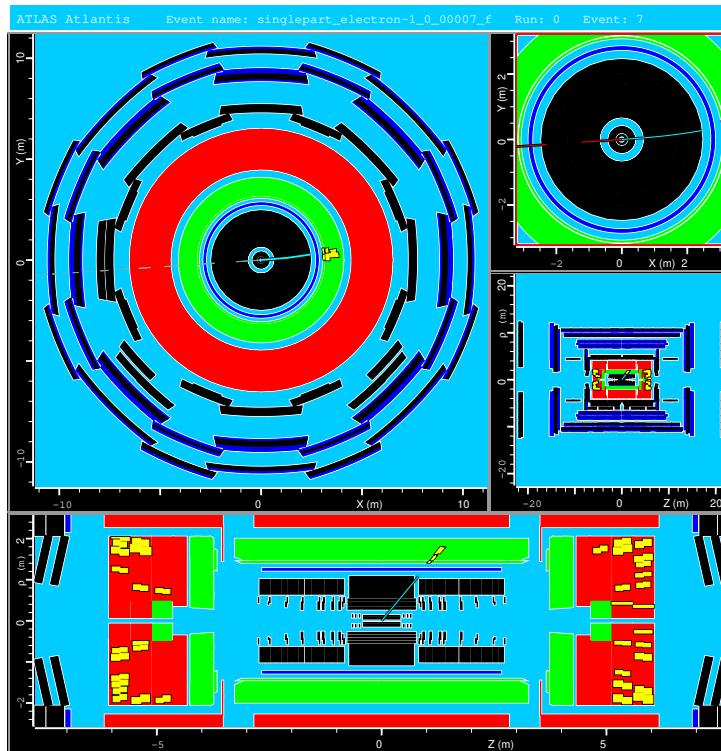

Figure 4.1.1: Event name: `singlepart_electron-1_0_00007_f`, Event: 7.

From this event, we observe that the electron, contrary to its electric charge, traverses without

bending. This is most likely due to the high momentum of the electron ($p_T = -6.030 \pm 0.097$ GeV), increasing the radius of curvature as shown in Eq. 2.2.1. We also observe signatures in the ECAL, indicating that the electron has produced an electromagnetic cascade, and has thus been absorbed completely. We also observe signatures in the HCAL, which are attributed to the background of the event. The \cancel{E}_T shown in the figure also result from background processes as $\cancel{E}_T \approx 61$ GeV, which is much larger than the electron momentum.

4.2 Muon Dataset

Fig. 4.2.1 shows Event 7 of the single muon dataset, where the signature of a single muon is observed.

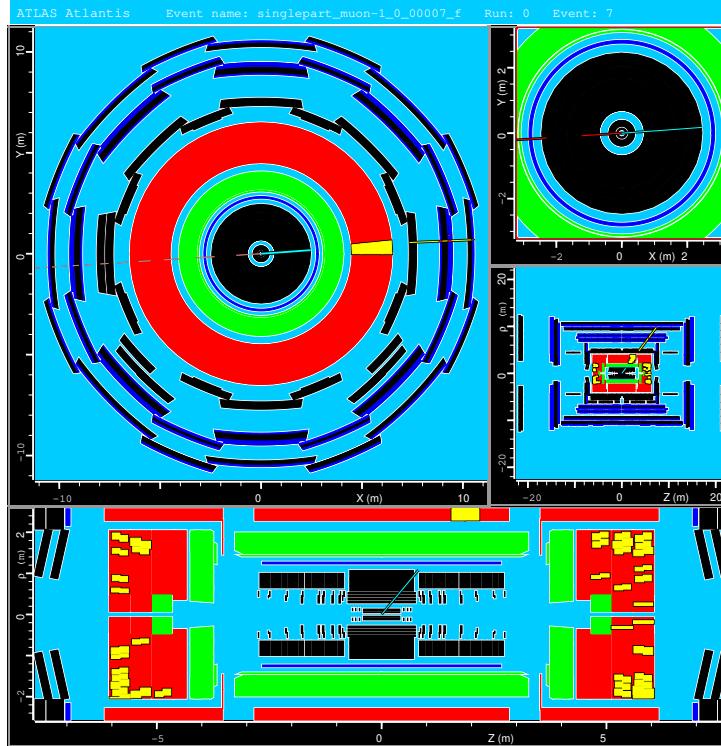

Figure 4.2.1: Event name: `singlepart_muon-1_0_00007_f`, Event: 7.

We observe that again, the muon trajectory looks relatively straight, which is attributed to its high momentum ($p_T = -51.820 \pm 1.070$ GeV). We also observe that the muon shows hits in the inner detector and the tracking detectors from the muon system as expected. However, we also observe some signature in the HCAL, which is most likely due to a top quark decay. Since the top quark decays to $t \rightarrow W^+ b$, and this W boson decays to $W^+ \rightarrow \mu^+ \nu_\mu$, we get a muon surrounded by jets and the neutrino going in the opposite direction to conserve momentum. Hence, we see a deposit in the HCAL followed by tracks in the muon tracker along the same path. The $\cancel{E}_T = 55.792$ GeV, which is close to the p_T of the muon. Thus the contribution from ν_μ may be contained within \cancel{E}_T .

4.3 Photon Dataset

Fig. 4.3.1 shows Event 18 of the single dataset for the photon.

We do not observe any signatures in the inner detector, but observe a single shower in the ECAL. This indeed matches the signature of a photon as they are electrically neutral and thus transparent to the tracking detectors. The energy deposition in each layer is around $E_T \approx 10 \sim 20$ GeV, indicating that the photon is energetic enough to undergo pair production or Compton scattering.

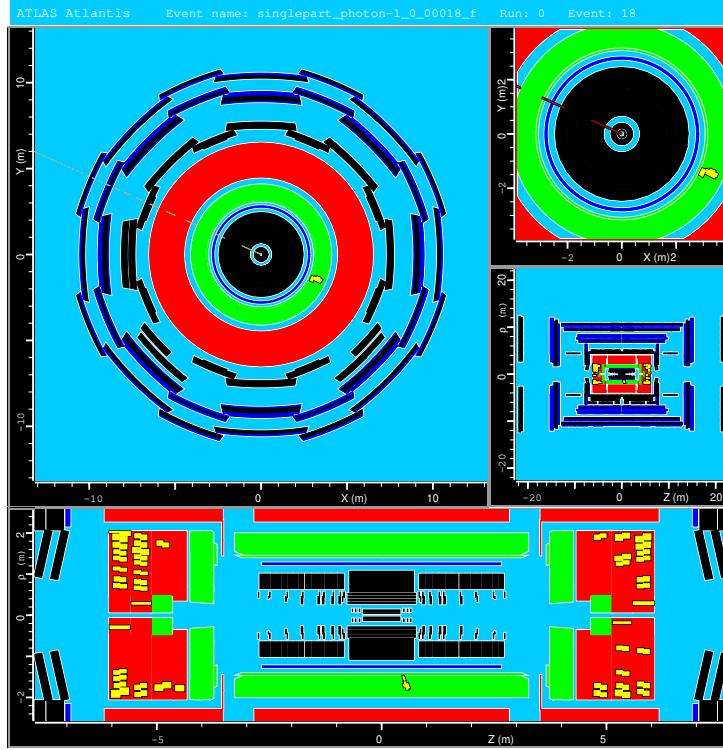

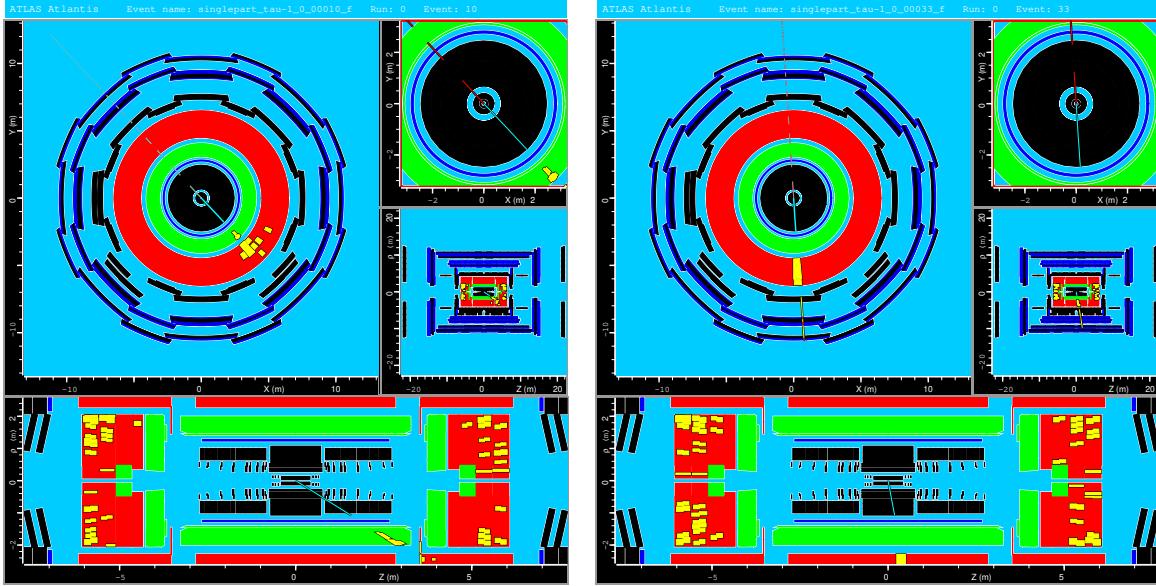

Figure 4.3.1: Event name: `singlepart_photon-1_0_00018_f`, Event: 18.

4.4 Tau Dataset

Fig. 4.4.1 shows Event 10 and 33 of the single dataset of the tau lepton.

(a) Event name: `singlepart_tau-1_0_00010_f`, Event: 10. (b) Event name: `singlepart_tau-1_0_00033_f`, Event: 33.

Figure 4.4.1: Signatures of tau leptons in the detector. (a) shows decays via hadrons and (b) shows signatures from leptonic decays.

In Event 10, we observe a collimated mini-jet that deposits signatures in both ECAL and HCAL. The energy deposition in the ECAL is most probably attributed to the photon pairs of the neutral pions produced within the mini-jets. The hadronic cascade in the HCAL is wide, which is due to the low

momentum of the mini-jet ($p_T = 26.230 \pm 0.636$ GeV). The value of the missing \cancel{E}_T is 28.298 GeV, thus \cancel{E}_T is most likely associated to the momentum of ν_τ .

We further observe that in Event 33, we observe a leptonic decay process which is around 35% of the branching ratio of the tau leptons. The event itself is indistinguishable from Event 7 in Fig. 4.2.1, thus making tau leptons that decay with this process much harder to detect.

4.5 Dijets Dataset

We now observe events that display signatures of two jets in the detector. Fig. 4.5.1 shows Event 15 in the relevant dataset. The upper right lower plot shows the 2-D histogram between the pseudorapidity η and azimuthal angle ϕ instead as it is more relevant for our discussion.

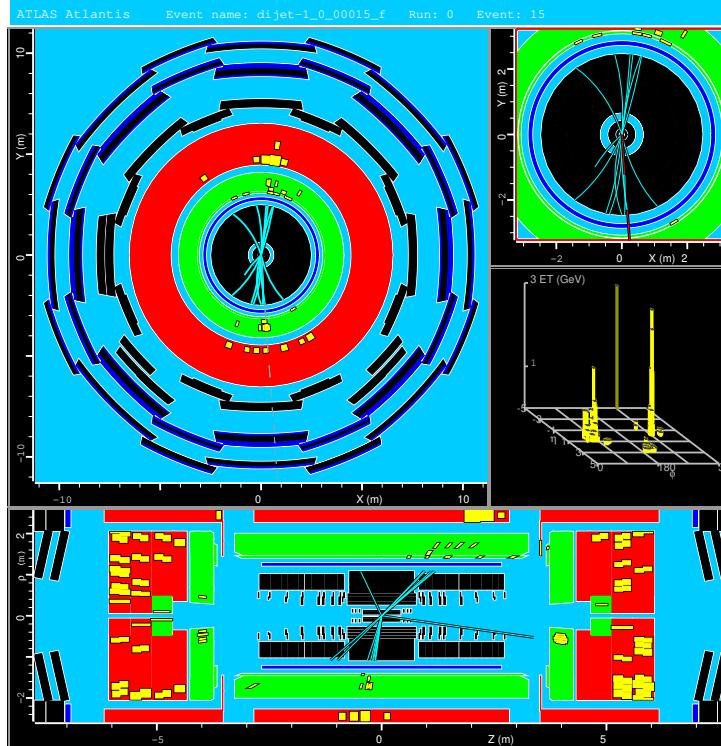

Figure 4.5.1: Event name: dijet-1_0_00015.f, Event: 15.

We observe two prominent jets generated opposite from each other in the transverse plane, where they are almost aligned with the y -axis. The two large peaks that are observed in the 2-D histogram also shows this behavior, where the azimuthal angle are approximately 180° from each other. We can identify them as jets as they produce hadronic cascades at the HCAL. They also show signature in the ECAL which is mostly from semi-leptonic decays coming from τ lepton or b-jets and the photon pairs due to neutral pion decays. We also observe two opposing trajectories (with opposing curvature) that only leave signatures in the ECAL. This is most probably an e^+e^- pair that is generated by pair production of photons. When observing the lower plot, we also observe an additional trajectory pair left to the lower jet with an energy deposition only in the ECAL. Using the “pick” command, we observe that the pairs have opposing curvatures with similar momenta, implying that these trajectories are from another e^+e^- pair.

4.6 Wenu Data set

In this data set, a W boson decays like, $W^+ \rightarrow e^-\bar{\nu}_e$ or $W^+ \rightarrow e^+\nu_e$. This means that the event will contain missing transverse momentum. In Fig. 4.6.1, we see the event 9 from the data set. Starting from the vertex, we see two curved tracks in the top left figure, which deposit their energy in the ECAL. On the opposite side we also notice a huge deposition of hadrons in the HCAL. In the same direction, there is also the line for the \cancel{E}_T . In the bottom figure, we see a huge number of deposits in the HCAL.

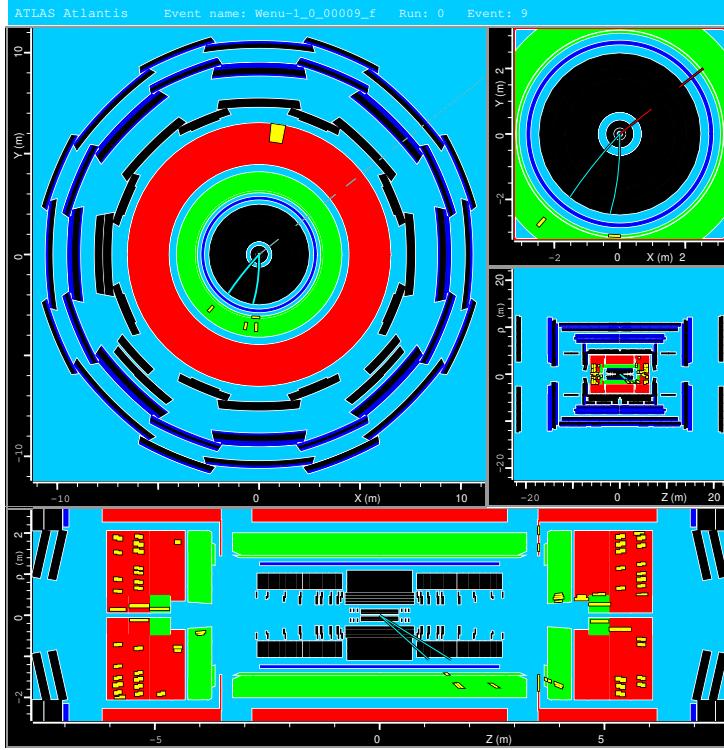

Figure 4.6.1: Event name: Wenu-1_0_00009_f, Event: 9.

Since the event contains the decay $W \rightarrow e\nu$, one of the tracks which is opposite the \vec{E}_T vector is mostly likely the electron from this decay. By using the pick function, we can see the details of \vec{E}_T , which are:

```
ETMis:
storegate key: MET_Final
Sum-ET = 45.688 GeV
ET-Mis = 31.907 GeV
ETx-Mis = 25.086 GeV
ETy-Mis = 19.716 GeV
phi = 38.165°
```

4.7 WFull Data set

Next, we study the `WFull-1-f.zip` data set. In this, all possible decays of W boson can be seen. In Fig. 4.7.1, starting from the vertex, several curved tracks emerge, indicating the presence of charged leptons and hadrons. Some curves disappear before reaching the ECAL, most likely due to their low momentum (sometimes called “soft” particles). The charged leptons leave their deposit in the ECAL and hadrons in the HCAL. For several deposits, we see an alignment, i.e., the jets contain leptons as well. This could be due to top quark, which decays to $t \rightarrow W^+b$, from which we get jets from the b quark and lepton and neutrino from the W .

The \vec{E}_T is found to be

```
ETMis:
storegate key: MET_Final
Sum-ET = 250.750 GeV
ET-Mis = 14.408 GeV
ETx-Mis = -12.976 GeV
ETy-Mis = 6.263 GeV
```

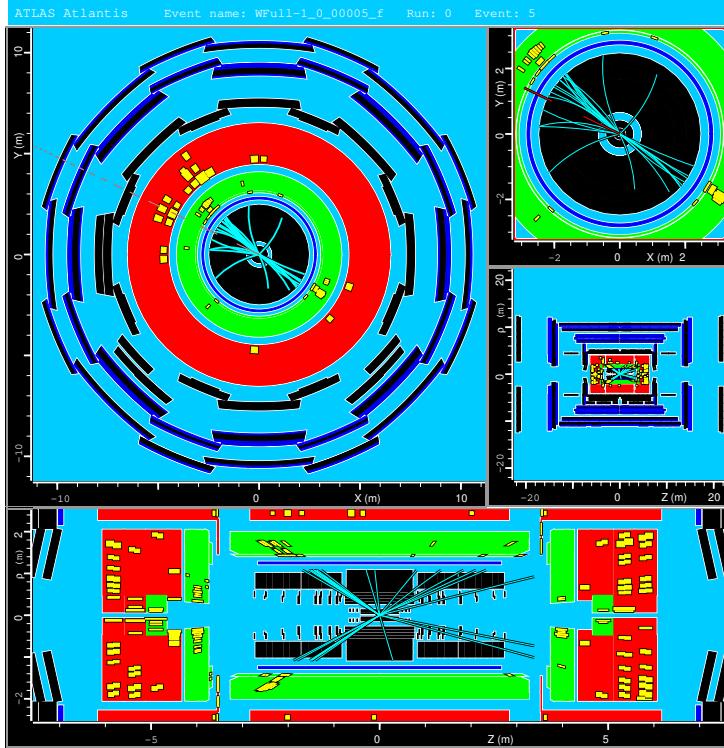

Figure 4.7.1: Event name: WFull-1_0_00005_f, Event: 5.

$$\phi = 154.236^\circ$$

which is quite high as compared to previous data set, indicating a high number of neutrinos and W boson decays in the event. Further, there is a high number of deposits in the forward sections in the HCAL. This is an expected behavior, since the angular distribution of final state hadrons increases strongly in the forward region [1].

4.8 Zee Data set

Now we look at the `Zee-1-f.zip` data set. In Fig. 4.8.1, we see the event 3. Similar to our previous discussion, we see several tracks followed by deposits in ECAL and HCAL, with the presence of \vec{E}_T . An interesting feature of this data set is that several ECAL deposits are often opposite to each other. This means that the mother Z^0 boson was most likely at rest when these electrons were produced, giving us this characteristic.

Next, we work with two of the assignments listed in the lab manual. Since we were allowed to pick the assignments on our own, we chose to work with the `mystery-035-f.zip` data set and `ATLASData-Cosmics-M5.zip` data set.

4.9 Assignment 7: Mystery Data Set

In this data set, a pre-selection is applied, in which at least two leptons (e or μ) are required to be in each event. The goal of this exercise is to look at the graphics and identify various Standard-Model processes by studying them. Further, we must try to rule out certain processes, if any. In Fig. 4.9.1, we see the graphical view of event 13. Fig. 4.9.2, gives us the zoomed in view of the vertex for the same event. We start our discussion from the vertex.

A zoomed in view of the vertex shows that most tracks originate from the vertex, but some are reasonably far away from the vertex. The tracks originating far away from the vertex must come from a particle which has decayed after a certain period of time. This gives us the following three possibilities for the original particle: τ^\pm lepton, top quark or b-quarks (b-jet). Since W and Z^0 boson decay almost

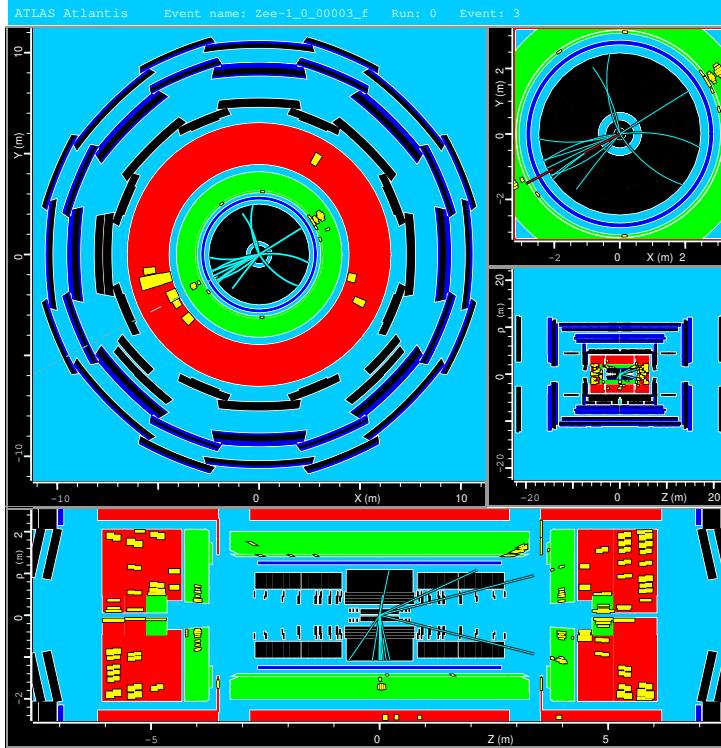

Figure 4.8.1: Event name: Zee-1_0_00003_f, Event: 3.

immediately, the track reconstruction resolution would not be able to pick on the slight differences in the vertex due to those decays.

As these particles start heading towards the detector, we see that charged particles are bent based on their momentum and leave a “hit” in the inner detector. Some particles are too “soft” and hence their tracks disappear before reaching the ECAL. Looking at the deposition at the ECAL and HCAL, we see that most depositions between them align with each other. This indicates the presence of charged electrons and photons in jets. We know that b-jets contain leptons, as in 25% of all B decays, a lepton is produced. We can get this b-quark from the top quarks via $t \rightarrow W^+b$. The figure in the bottom half also shows the presence of isolated jets, without leptons. Since τ leptons can decay purely to hadrons and neutrinos, one of the ways to identify them is to look for collimated “mini” jets.

Two other interesting tracks we see in the ECAL and HCAL are the isolated depositions in ECAL which do not have a corresponding deposition in the HCAL. This means that these charged electrons can come from the following sources: photons, W bosons, Z^0 bosons and τ leptons. The presence of missing energy in the event confirms the existence of neutrinos and hence, confirms the possibility of W boson decays. The other interesting track corresponds to the deposition in HCAL and then a track in the muon detector. This confirms the presence of muons in the event, which was probably surrounded by jets. This could be either due to top quarks or b-quarks.

We look at one more event in Fig. 4.9.3, event 12. In this event as well, we see all of the properties discussed above. Some thing which are slightly different is a higher number of isolated deposits in ECAL (without the corresponding deposit in HCAL) and the presence of two muons instead of a single one, both in the presence of jets. By selecting the missing energy track, we can look at the numbers. The following output was shown in the terminal:

ETMis :

```
storegate key: MET_Final
Sum-ET = 1087.585 GeV
ET-Mis = 30.292 GeV
ETx-Mis = -30.055 GeV
ETy-Mis = 3.781 GeV
phi = 172.829°
```

Since the \cancel{E}_T is quite high, we can confirm the existence of one or more neutrinos in the event. Based

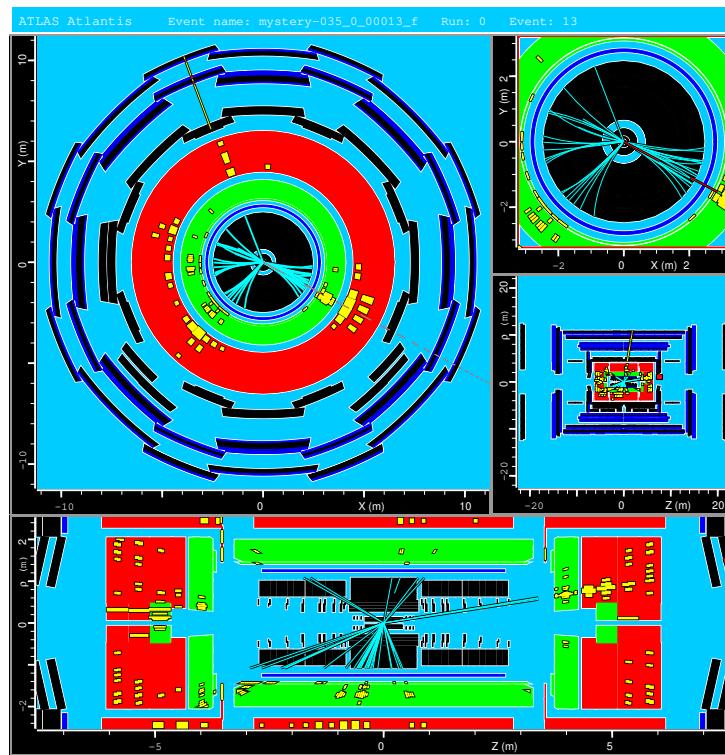

Figure 4.9.1: Event name: `mystery-035-f`, Event: 13.

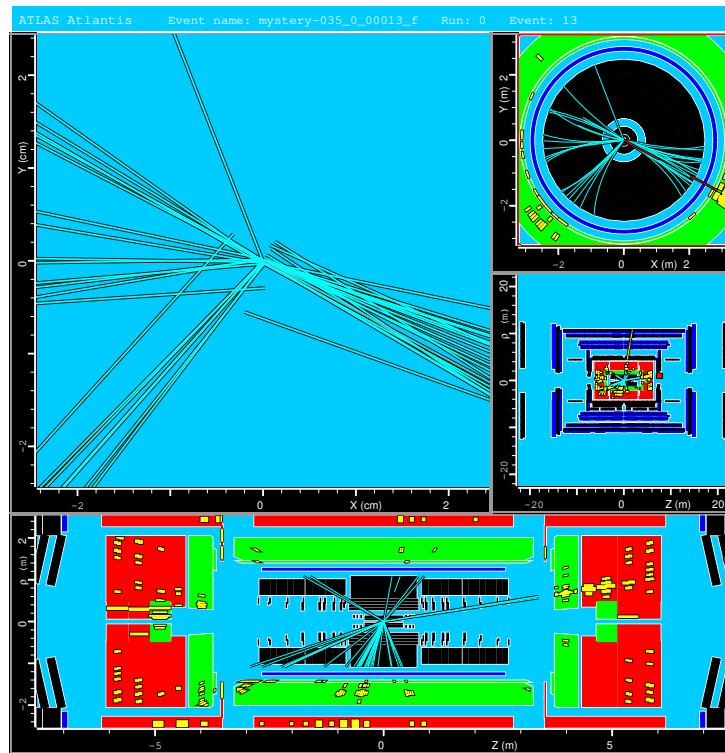

Figure 4.9.2: Event name: `mystery-035-f`, Event: 13.

on the discussion above, it is not possible to rule out any SM process for two lepton events.

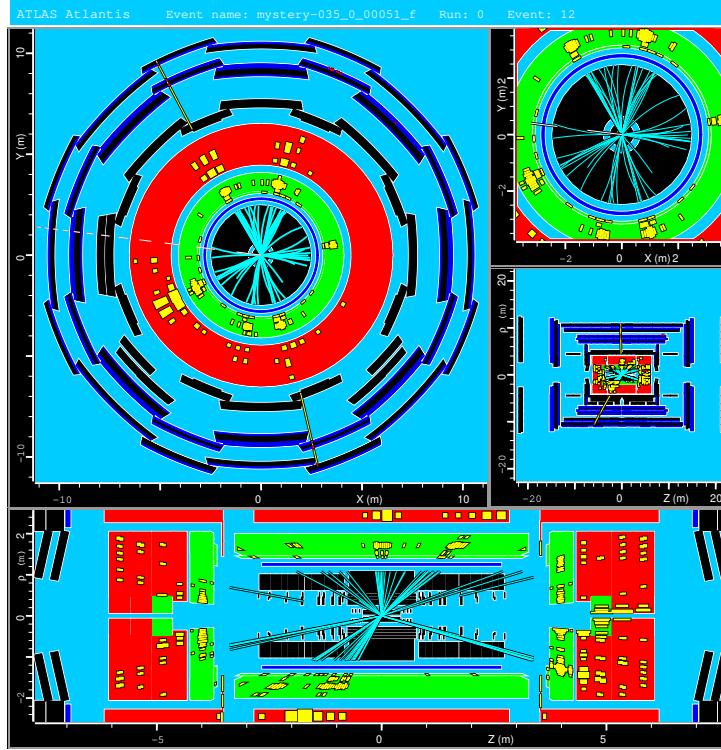

Figure 4.9.3: Event name: `mystery-035-f`, Event: 12.

4.10 Assignment 8: Cosmic Ray Dataset

In this part of the assignment, we investigated the angular distribution of muons originating from pion decay from air showers in the atmosphere that are detected from the muon chambers in the ATLAS detector. Real ATLAS data from 2007 and 2008 was used in this assignment, contained in the provided file `ATLASData-Cosmics-M5.zip`.

Fig. shows an example of an event observed with this dataset. Note that we have chosen different projections as compared to the figures shown in Sec. 4.9 as the projections in such previous figures do not provide any new information in this assignment. We observe that no signatures have been observed in the inner detector as well as in both ECAL and HCAL. This is expected as these muons have momentum of the order of 1 GeV, and as such they do not emit bremsstrahlung and thus no showers are formed in the calorimeters.

To determine the angle in which the muon has entered the detector, we determined the azimuthal angle ϕ_0 relative to the ATLAS detector. This is obtained by using the "pick" option in the ATLANTIS program to select each muon track in each event in this dataset. The azimuthal angle was then converted into the zenith angle, i.e. the angle from the local zenith. As $\phi_0 \in [0, 2\pi]$ where $\phi_0 = 0$ is at the positive x-axis, and $\theta \in [-\pi, \pi]$ where $\theta = 0$ is at the local zenith, an azimuthal angle of $\phi_0 = \pi/2$ will be equivalent to $\theta = 0$ as the local zenith is parallel to the y-axis in the detector. Following this logic, we can derive the transformation between ϕ_0 and θ as such:

$$\theta = \begin{cases} \phi_0 - \frac{\pi}{2} & : \phi_0 < \frac{3\pi}{2} \\ (\phi_0 - \frac{\pi}{2}) - 2\pi & : \phi_0 > \frac{3\pi}{2} \end{cases}. \quad (4.10.1)$$

See Appendix A for a more detailed schematic of the transformation.

Fig. 4.10.2 shows the corresponding angular distribution from the cosmic ray muons observed in this dataset, along with the expected distribution $\cos^2(\theta)$ at sea level. Note that we only plot from -90° to 90° as muons produced from beyond the horizon originate from air showers with an extremely low probability.

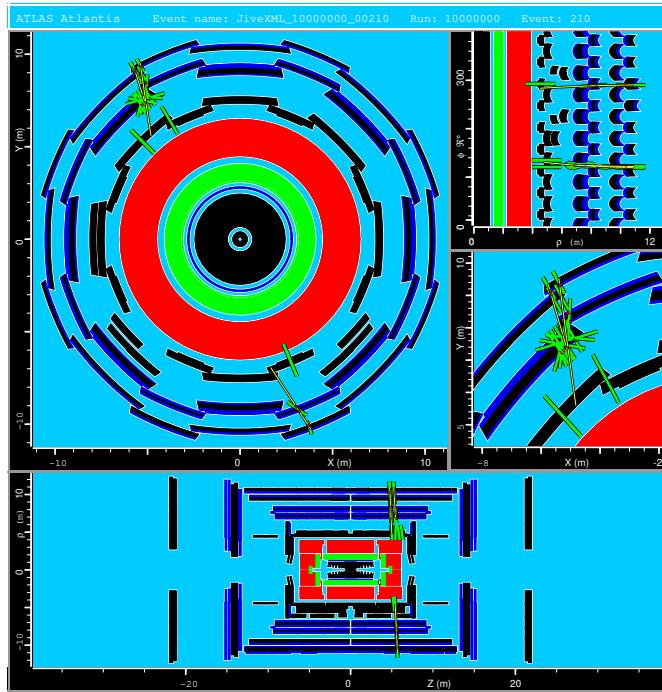

Figure 4.10.1: An example event for cosmic ray muons (Event 210). The reconstructed muon tracks are shown in yellow.

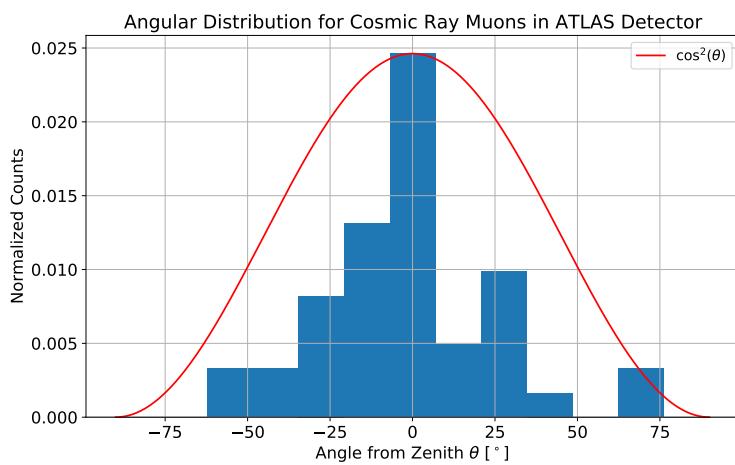

Figure 4.10.2: Angular distribution of cosmic ray muons observed from the ATLAS detector in 2007 and 2008. The expected $\cos^2(\theta)$ is also shown.

We observe that while the muon intensity decrease with larger zenith angle, the distribution does not follow a $\cos^2(\theta)$ distribution. This can be attributed to several reasons. Firstly, the ATLAS detector is located 100m below ground, and as such the muons with higher incoming angle will be stopped more by the underground material as compared to those near the zenith. Further, as there are two access shafts located above the ATLAS detector, muons with higher incoming angles interact less with underground material [14]. As such the distribution behaves like $\cos^n(\theta)$ with the exponent $n > 2$. Another reason for this is due to the low statistics, as the total number of events is $N_{\text{ev}} = 65$. With more events, the histogram will be smoother and thus will be able to discern whether the distribution behaves as $\cos^2(\theta)$ or not.

Chapter 5

Calibration of Electrons

Before performing the measurement of the W mass, the data needs to be calibrated. In this experiment, the raw data was supplied to us and we first have to improve its quality. The most accurate way to determine the energy of electrons is by measuring the deposit in the ECAL. There are several reasons for calibration:

1. The detector consists of hundreds of modules, which will return unequal energy.
2. There could be several parts of the calorimeter which might be inactive.
3. The electron loses a part of its energy in the silicon tracking region before depositing its energy in the calorimeter.

For these reasons, the raw energy values are lower than the true value. Calibration is the way to fix that.

The mass of the Z^0 boson is a well known parameter of the SM. It has been measured to a precision of 2×10^{-6} relative uncertainty. The width has been measured upto 1 per thousand. Further, we know that most of the electron-positron pairs in an event originate from Z^0 . Hence, the Z^0 peak, which is a well known signal, can be used in order to calibrate our data.

To perform this calibration, we use the library `fitZee.C`, which takes the calibration from the file `ElecCalib.C` and applies that to the data. Applying changes to the `ElecCalib.C` file and compiling `fitZee.C` also changes the `z.Fit()` command. After activating `root`, the following commands are run:

```
.L fitZee.C+
fitZee z
z.Fit("")
```

This creates a calibration object “`z`” which will be used to calibration. The `z.Fit("")` command fills the histogram and applies the best fit and outputs the fit parameters. The output of this command is shown in Fig. 5.0.1. The Z mass for the uncalibrated data is found to be 89.87 ± 0.02 GeV and resolution is 2.588 ± 0.026 . In the calibration process, the aim is to get the mass as close as possible to the ideal value, which is 91.1876 ± 0.0021 GeV. Further, the resolution should also be decreased by at least 0.2, while trying to get a good χ^2/ndf value (ndf stands for number of degrees of freedom). A value of approximately 1 is ideal. χ^2 characterizes the fit quality and the aim is to usually minimize it. Therefore, a high χ^2 signifies a bad fit.

One can also look at fits with cuts, i.e., looking at how the fit changes for different regions of the parameter spectrum. For instance, to look at the fit in the different regions of the azimuthal angle ϕ , the following command can be run

```
z.Fit("el_phi>0. && el_phi<0.4")
```

Thus, passing the cuts in the fit command allows us to probe different regions of the parameters. The some of the available variables are `el_pt` (transverse momentum of electron), `el_eta` (psuedorapidity), `el_energy` and several others. After applying cuts in several ranges, one can run `z.List()` and looking at the numbers corresponding to different ranges, stack them in the single plot by running

```
z.Draw(0, 1, 2, 3)
```

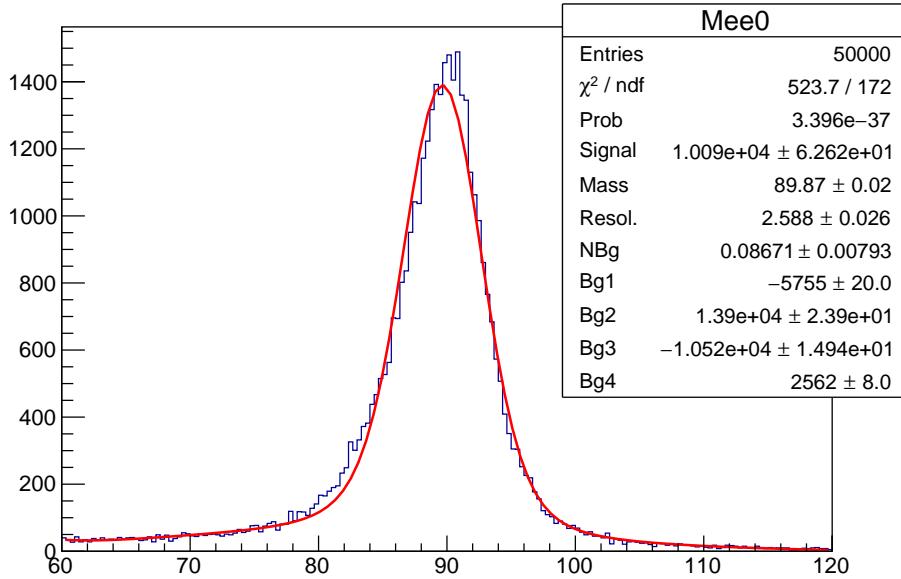

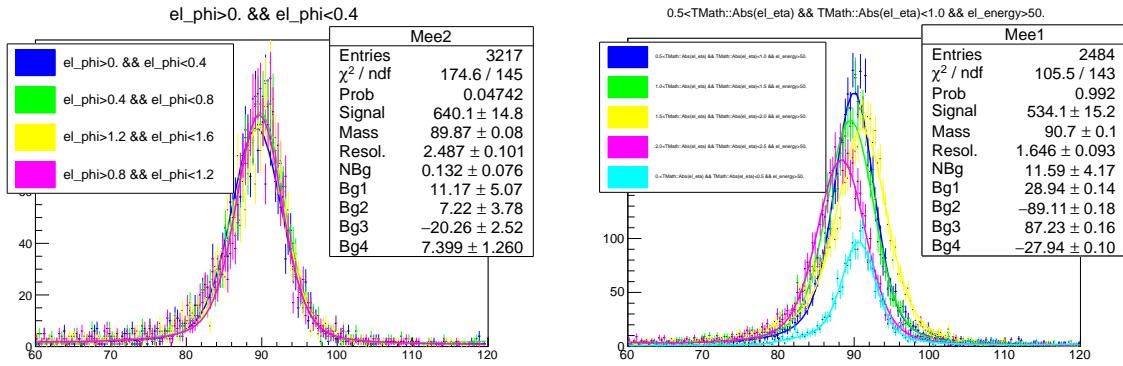

Figure 5.0.1: The output of the uncalibrated data. A resonance near the Z mass can be seen. The red line is the fit and the legend contains the fit parameters.

(a) Stacked reconstructed fits of different azimuthal angle, ϕ , regions.
(b) Stacked reconstructed fits of different pseudorapidity, $|\eta|$, regions.

Figure 5.0.2: Stacked plots of different parameters in different regions. We notice a shift in the peak for different regions.

An example of this is shown in Fig. 5.0.2. A shift in the peak can be seen for different regions. These regions must be studied and calibration must be applied to them. After applying the calibration for several regions, the output is observed and the process is repeated for several more regions and variables. After several trial and errors, we were able to get the desired calibration.

After applying cuts for different regions of a single variable, the calibration was applied and the output was looked at. Then, with this applied calibration, different regions of another variable were compared as mentioned above and the calibration file was modified to correct for this variables. This was done for these set of variables in the following order: phi, eta, mindrjet (which is the minimum distance of the electron to the nearest jet in the $\eta\phi$ plane), etiso (transverse energy of the electron in the area surrounding it in the calorimeter) and pt (transverse momentum). The corresponding plots are shown in Fig. 5.0.3 and the final calibration plot is shown in Fig. 5.0.4. The corresponding code can be found in the Appendix B.

Thus, we were able to get the mass to be 91.198 ± 0.0196 GeV and the resolution to be 2.342 ± 0.024 . χ^2/ndf is found to be $464.6/172 \approx 2.7$. Using the command `z.Compare()`, we can see the effect of

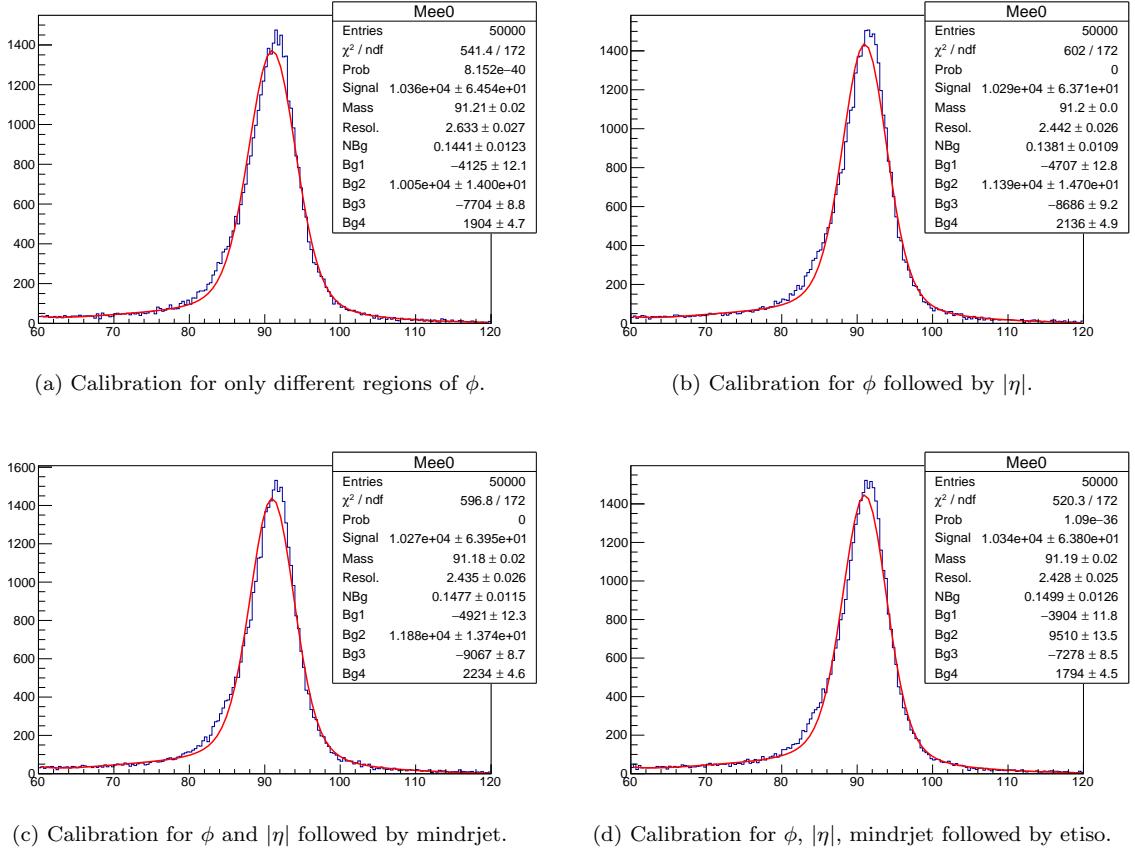

Figure 5.0.3: Calibration applied one after the other for different set of variables.

calibration on the data, in Fig. 5.0.5. Further, we also notice a change in the values of mass, resolution and χ^2/ndf . This is because the `Compare()` function uses the “LARGE” argument in the `Fit()` function, which uses all the data. By running `z.Fit("", "LARGE")`, the change in the values was confirmed.

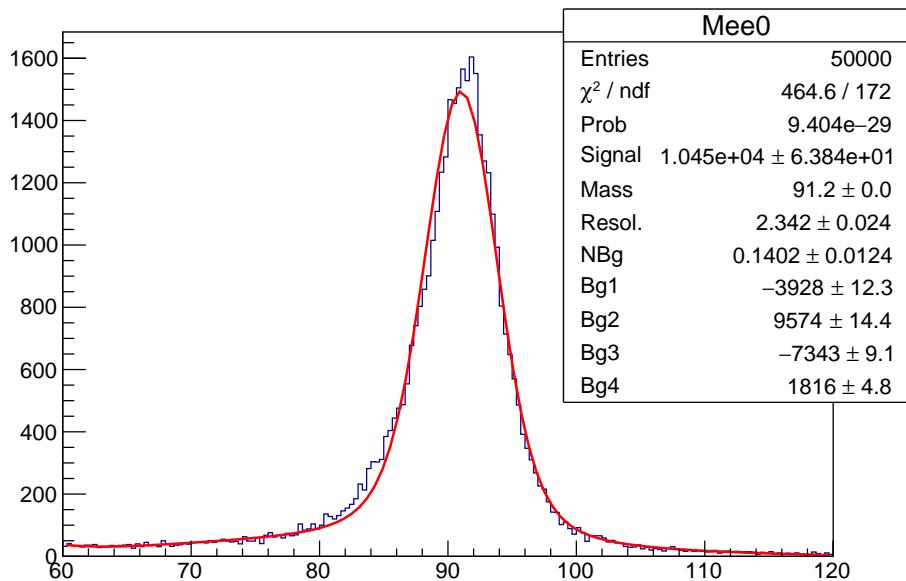

Figure 5.0.4: The final fit curve after applying ϕ , $|\eta|$, mindrjet, etiso followed by p_T calibrations.

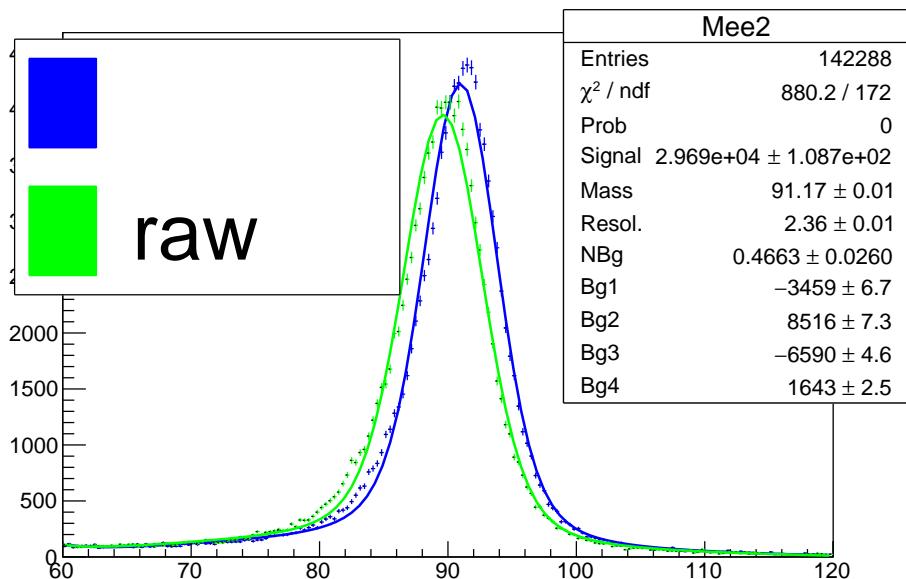

Figure 5.0.5: Comparison between calibrated and uncalibrated data. The blue fit corresponds to calibrated data and the green to the uncalibrated data.

Chapter 6

Measurement of the W boson Mass

In this section, we elaborate on the methods used to determine the W boson mass using real ATLAS data. As mentioned in Sec. 2.3, there are several methods to determine the mass of the W boson. In this experiment, we measure this mass by observing the position of the Jacobi peak from the electron p_T distribution resulting from $W \rightarrow e\nu$ events.

In this experiment, we were given several datasets, mostly containing simulated $W \rightarrow e\nu$ events with different W boson masses and real ATLAS data for the same process. A dataset containing real ATLAS data from $Z \rightarrow ee$ events are also contained, used to verify that the gauge curves retrieve the Z^0 boson mass accurately, which is known more accurately than the W boson mass. A list of the datasets is shown in Table 6.1.

In addition to the W and Z^0 boson datasets, two additional datasets relating to the QCD and non-QCD backgrounds are contained. The QCD background dataset are generated from proton-proton collisions where the hard interactions are strong. As it is difficult to simulate the QCD events containing electrons, this background is extracted directly from real ATLAS data instead. While this matches the shape of the QCD backgrounds in the W and Z^0 boson datasets, the integrated luminosity are not equal and thus a proper normalization using a scale factor is required for our analysis. The non-QCD backgrounds are extracted from simulated events [1].

For all parts of the analysis, we use ROOT and use the C++ library `Wenu.C+` to load the C++ object used in the analysis. This is loaded with the following commands:

```
.L Wenu.C+
Wenu w
```

6.1 Verification of Electron Calibration

We first verify if our calibration of the electron momentum performed in Chap. 5. This is done by running the `FitZee` function which acts similarly to the same function in Chap. 5. We observed this

Dataset Abbrv.	Description
<code>Wenu</code>	Real ATLAS data for $W \rightarrow e\nu$ candidate events
<code>Zee</code>	Real ATLAS data for $Z \rightarrow ee$ candidate events
<code>MCW75</code>	Simulated events with $m_W = 75$ GeV
<code>MCW78</code>	Simulated events with $m_W = 78$ GeV
<code>MCW79</code>	Simulated events with $m_W = 79$ GeV
<code>MCW / MCW80</code>	Simulated events with $m_W = 80$ GeV
<code>MCW81</code>	Simulated events with $m_W = 81$ GeV
<code>MCW82</code>	Simulated events with $m_W = 82$ GeV
<code>MCW85</code>	Simulated events with $m_W = 85$ GeV
<code>QCD</code>	QCD background events extracted from ATLAS data
<code>non-QCD</code>	non-QCD backgrounds obtained from simulated data

Table 6.1: List of datasets available for this experiment. The abbreviation used to use such datasets in ROOT is provided.

distribution for 4 kinematical regions of interest. The obtained histogram from applying no cuts is shown in Fig. 6.1.1.

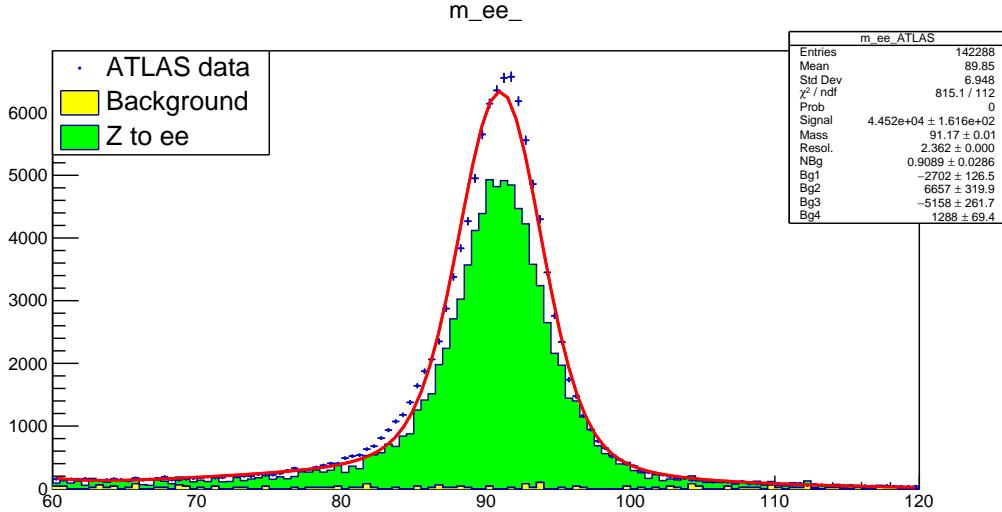

Figure 6.1.1: The invariant mass distribution of ee from $Z \rightarrow ee$ decays without applying any cuts. The blue points are the real data from ATLAS, the red line is the Voight function fit, and the green histogram is the simulated data. The background is also shown in yellow.

We observe that the invariant mass for the e^+e^- pair is given as 91.17 ± 0.01 GeV, which agrees with the world average value of the Z^0 boson mass of 91.1876 ± 0.0023 GeV within 1.76 sigma [2]. While this may not be within 1σ , as we did not prudently calibrate the dataset for all possible parameters, we agree that the calibration is indeed properly set for our analysis.

We also observe the invariant masses for the same distribution with different cuts: `el_energy < 50` ($E_e < 50$ GeV), `el_eta < 1` ($\eta < 1$), and `el_pt < 40` ($p_{T_e} < 40$ GeV). explain why we used these energy cuts? (pseudorapidity since central region - ζ , high number of particles) See Appendix A for the invariant mass distributions for each cut. From these distributions, we obtain the following invariant masses for each cut respectively: 90.93 ± 0.02 GeV, 91.14 ± 0.01 GeV, 90.94 ± 0.02 GeV. When comparing with the world average value, we observe that they are also close to the Z^0 boson mass, with the largest deviation of 0.25 GeV. This shows that even with cuts applied, the Z^0 boson mass is calibrated to an acceptable range.

6.2 Kinematic Parameters and Preliminary QCD Scaling

Once we have verified that our calibration is properly applied, we observe the distributions for ATLAS data compared with simulated data for different relevant parameters. In our analysis, we observed the following parameters: `el_pt`, `el_etiso`, `njet`, `etmis`, and `ptw`. In the following sections, we highlight the importance of each parameter. The distributions were constructed by the following command:

```
w.PlotW(PARAMETER, BINS, XMIN, XMAX, CUTS).
```

The transverse momentum distribution for electrons, which is most relevant to us for determining the Jacobi peak, is shown in Fig. 6.2.1. See Appendix A for the distributions for the other parameters with no cuts applied.

From the p_T distribution of electrons, we observe that the amplitude of the simulated data (and the backgrounds) are much higher than the real data. This is caused by the uncalibrated scaling of the QCD background, and as such we set a scale factor so that the two data coincide. To do this, we use the function `w.SetQCDScaleFactor(VALUE)` and we set a preliminary value of 0.3. See Fig. 6.2.2 for the effect on applying such scale factor to the electron p_T distribution.

In the following sections, we will refine the scaling parameter after applying cuts and setting fitting ranges.

To obtain a sharp Jacobi peak, we want to reduce the smearing of the peak as much as possible. One factor that contributes to such smearing is the transverse momentum of the W boson p_{T_W} as mentioned

el_pt_

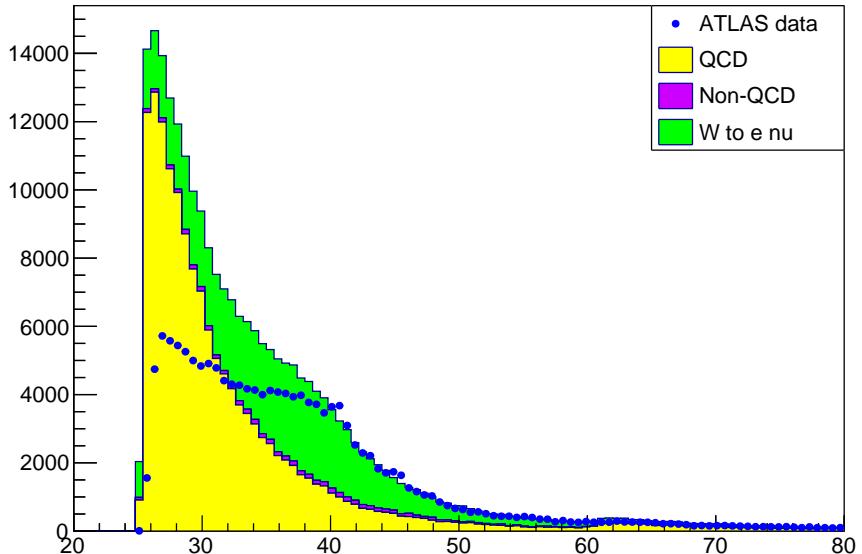

Figure 6.2.1: The transverse momentum distribution for electrons for the W boson decay with no cuts applied. The blue points are the ATLAS data, the green histogram is the simulated $W \rightarrow e\nu$ decays, and the yellow and purple histograms are the QCD and non-QCD backgrounds respectively.

el_pt_

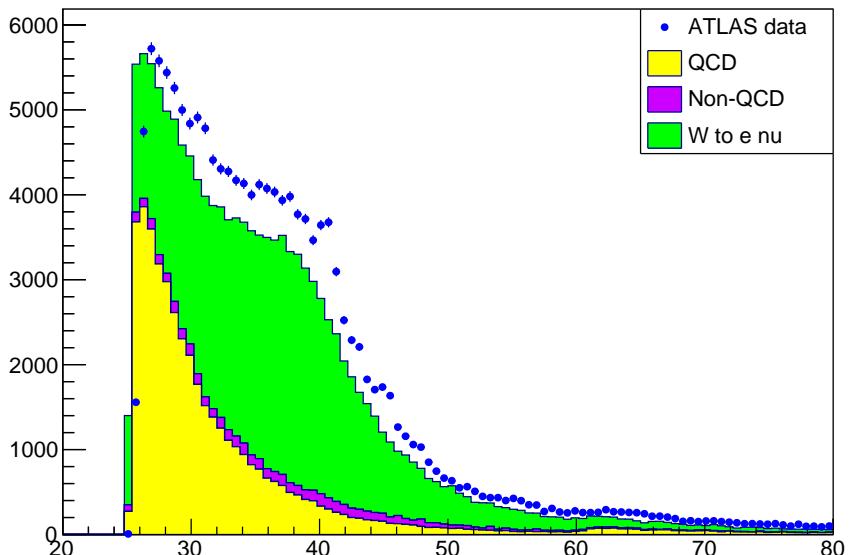

Figure 6.2.2: Same as Fig. 6.2.1 but applying the QCD scale factor of 0.3 instead.

in Sec. 2.3. To reduce this, we filter events in which several jets are produced. The W bosons obtained from such events suffer recoil from the quarks and gluons produced with the proton-proton collision, yielding a finite W boson transverse momentum. This is shown in the p_{T_W} distribution for different number of jets in Figs. 6.2.3 and 6.2.4. For events with no jets, the distribution is sharply peaked close to zero, however the peak shifts to $p_{T_W} \approx 50$ GeV for events with one or more jets. We also observe that the number of events decrease as we increase the number of jets, indicating that the dominant events are those with no jets. We further observe from these distributions that the QCD background increases as the number of jets increase due to the number of QCD processes involved. For the distributions with three and four jets, the QCD background overlaps the simulated data itself.

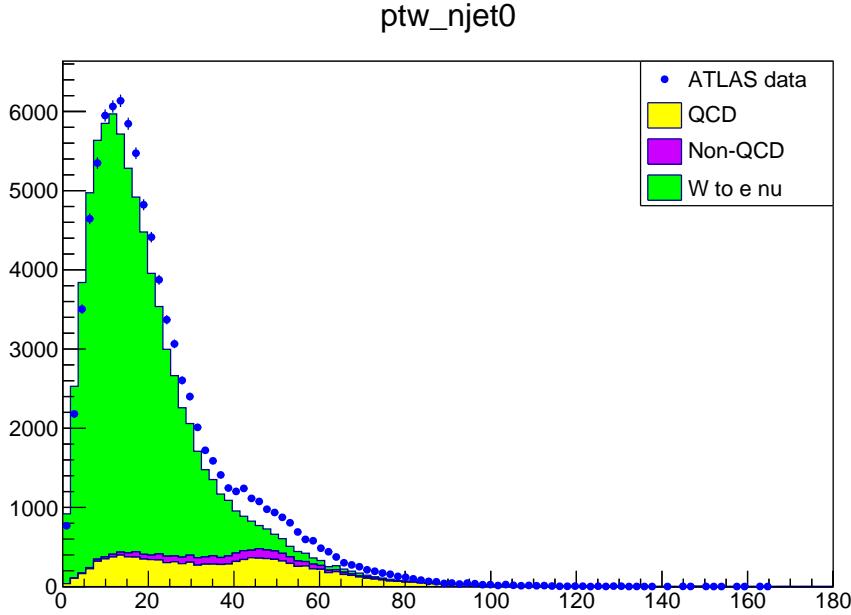

Figure 6.2.3: Transverse momentum distribution for W boson in W boson decay with no jets. The color code follows from Fig. 6.2.1.

From such plots, we observe that in order to reduce p_{T_W} and thus reduce the smearing of the Jacobi peak, we should set a cut of the number of jets such that events with no jets are chosen. **if works, add stuff about cut of W boson momentum too**

6.3 QCD Scale Factor and Cut Selection

In order to properly set the QCD scale factor, we use the `el_etiso` distribution. The parameter `el_etiso` represents the number of electrons observed within a cone of jets with $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.45$. This parameter is relevant as it quantifies the amount of QCD background events surrounding the electrons used to construct the electron p_T distribution. Thus to scale the QCD background, we observe the distribution where $\text{el_etiso} < 10$ GeV. In our analysis, we set the scale factor to be 0.30. Fig. 6.3.1 shows the `el_etiso` distribution in the full range and in the high QCD background range before and after setting the scale factor. We observe that applying our set scale factor yields amplitudes close to the real ATLAS data.

To estimate the uncertainty due to the QCD scale factor, we varied the scale factor until the deviation between the real data and the simulated data was significant (by eye). From this we, chose that the scale factor is acceptable between 0.28 and 0.30. See Appendix A for the distributions in the full range and in the high QCD background region for the two scale factors mentioned. This will be important in quantifying the systematic errors for the W boson mass.

From the above discussion, we require that we need to have events with no jets to reduce the transverse momentum of the W boson and to have `el_etiso` < 10 GeV to reduce events from the QCD background. After investigating the optimal value of `el_etiso`, we set the following cuts: `njet == 0` and `el_etiso < 8`. Fig. 6.3.2 show the p_{T_W} distribution before and applying such cuts. We also verified that after

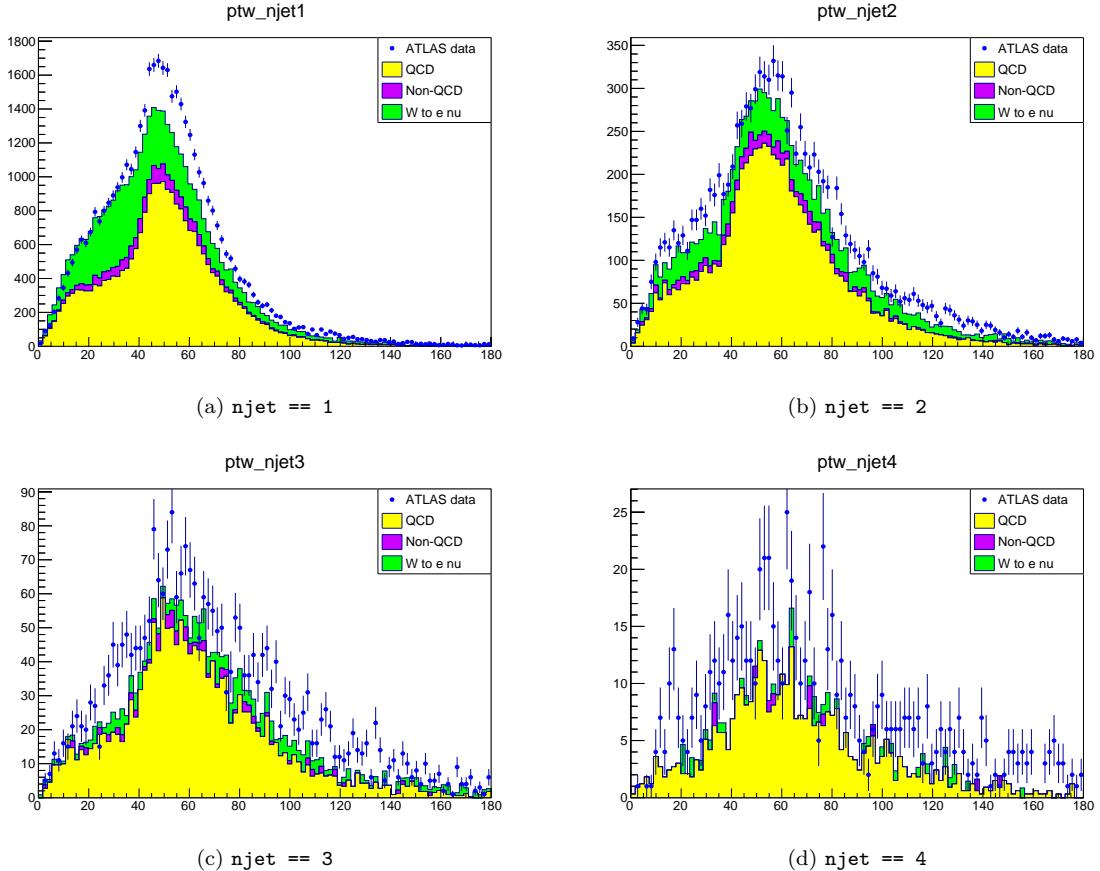

Figure 6.2.4: Same as Fig. 6.2.3 but for finite number of jets.

a	b [GeV]	χ^2
0.5214 ± 0.0080	$1.04 + -0.64$	8.68

Table 6.2: Parameters obtained from fitting the gauge curve.

applying such cuts, the QCD scaling factor is still valid. From this figure we observe that the impact from the QCD backgrounds is suppressed in higher p_{T_W} values as expected.

6.4 Gauge Curve

We now apply the fit provided in ROOT to obtain the half-maximum of the electron p_T distribution. This was performed using the command `w.GetHalfMaximum(DATASET, XMIN, XMAX)` for each simulated dataset given in Table 6.1, corresponding to masses $m_W = 75, 78, 79, 80, 81, 82$, and 85GeV . To efficiently run this portion of the analysis, a macro file `WMacro.c` was constructed (see Appendix B). The resulting half-maximum plots for each mass is shown in Appendix A. Here we show the results for $m_W = 80\text{ GeV}$ as an example, shown in Fig 6.4.1. For this analysis, we used the fitting range of $[28, 60]$.

Once we obtain the half-maximum from each fit, we apply a linear fit to directly relate the mass of the W boson and the obtained half-maximum h as such:

$$h = a \cdot m_W + b \quad (6.4.1)$$

This line is called the gauge curve. The corresponding gauge curve for the seven masses is shown in Fig. 6.4.2. The linear fit was evaluated by the Python module `lmfit` that utilizes the Levenberg-Marquardt method. Table 6.2 shows the obtained parameters from the fitting procedure.

The covariance matrix obtained from the fit is shown as such:

$$\begin{pmatrix} \sigma_a^2 & \sigma_{ab} \\ \sigma_{ab} & \sigma_b^2 \end{pmatrix} = \begin{pmatrix} 6.48 \times 10^{-5} & -5.19 \times 10^{-3} \\ -5.19 \times 10^{-3} & 4.16 \times 10^{-1} \end{pmatrix}. \quad (6.4.2)$$

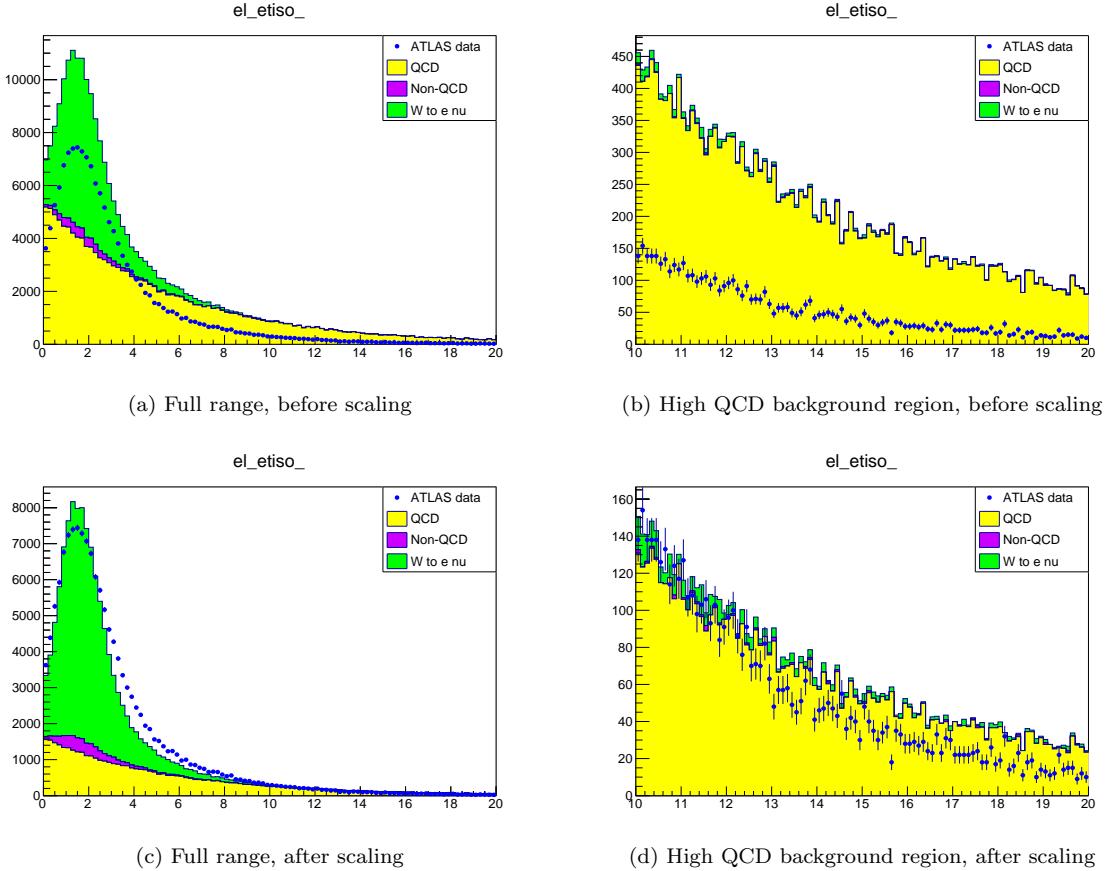

Figure 6.3.1: `el_etiso` distribution before scaling (top) and after scaling (bottom) for the whole distribution (left) and in the region with high QCD background (right). The QCD scale factor was set to 0.30.

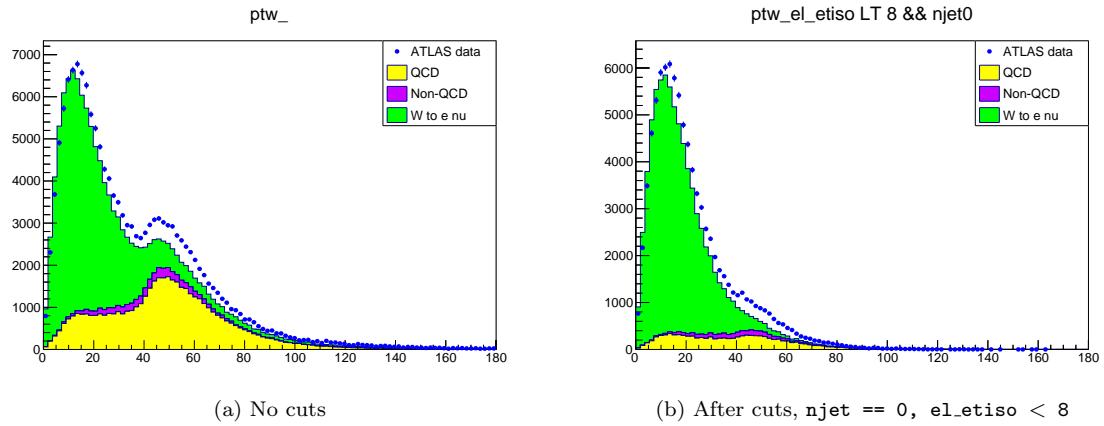

Figure 6.3.2: W boson transverse momentum distribution (a) before and (b) after applying cuts. The cuts `njet == 0`, `el_etiso < 8` was applied.

As the degrees of freedom is $ndof = 7 - 2 = 5$, we observe that the reduce chi-squared $\chi^2/ndof = 1.74$, which is close to 1, indicating that the fit is good.

Using the obtained gauge curve, we can now determine the mass of the W boson from the real ATLAS data. To do this, we get the half-maximum of the real ATLAS data by using the same command `w.GetHalfMaximum` for the ATLAS dataset `Wenu`. From this, we obtain the half-maximum to be $h = 42.989 \pm 0.049$ GeV. See Fig. 6.4.3 for the electron p_T spectrum with the ATLAS data. The mass of the

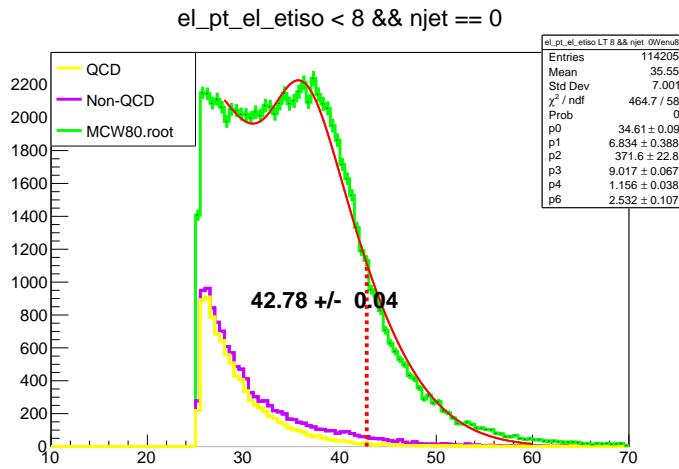

Figure 6.4.1: Half-maximum fit of electron p_T spectrum for simulated data with $m_W = 80$ GeV.

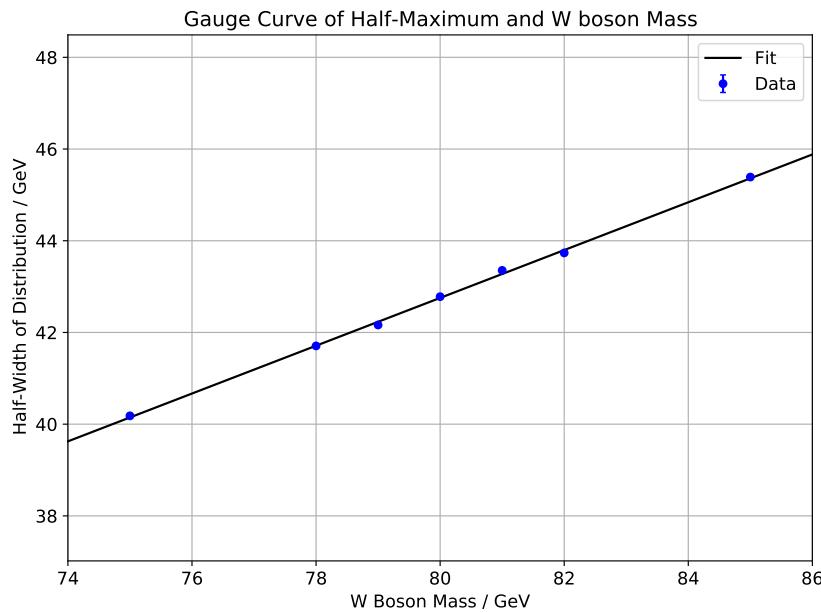

Figure 6.4.2: Gauge curve between half-maximum from fit with simulated data against W boson mass.

W boson is then obtained by rearranging 6.4.1 so that:

$$m_W = \frac{h - b}{a}. \quad (6.4.3)$$

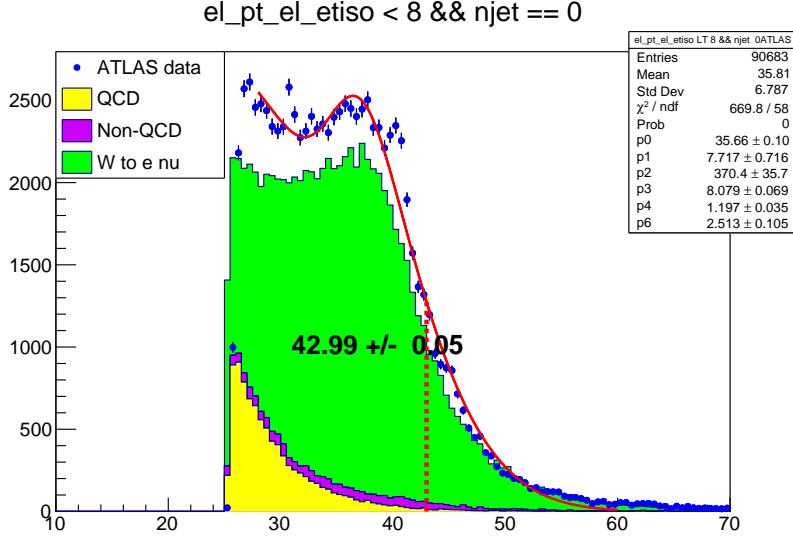

Figure 6.4.3: Same as Fig. 6.4.1 but for the real ATLAS data.

From this, we obtain the mass of the W boson as such:

$$m_W = 80.45 \pm 0.10 \text{ GeV} \quad (6.4.4)$$

where the error is evaluated by the following:

$$\sigma_{m_W} = \sqrt{\left| \left(\frac{\partial m_W}{\partial h} \sigma_h \right)^2 + \left(\frac{\partial m_W}{\partial a} \sigma_a \right)^2 + \left(\frac{\partial m_W}{\partial b} \sigma_b \right)^2 + 2 \left(\frac{\partial m_W}{\partial a} \right) \left(\frac{\partial m_W}{\partial b} \right) \sigma_{ab} \right|} \quad (6.4.5)$$

$$= m_W \sqrt{\left| \left(\frac{\sigma_h}{(h - b)} \right)^2 + \left(\frac{\sigma_a}{a} \right)^2 + \left(\frac{\sigma_b}{(h - b)} \right)^2 + 2 \left(\frac{\sigma_{ab}}{a(h - b)} \right) \right|} \quad (6.4.6)$$

$$(6.4.7)$$

where $\sigma_a, \sigma_b, \sigma_h$ are the uncertainties obtained from the fit parameters and the uncertainty from the half-maximum fit, and σ_{ab} are related to the correlation coefficients from the covariance matrix of the fit as shown in Eq. 6.4.2. Here, the error is purely statistical. We observe that our result is 0.18σ from the most recent value of the W boson of 80.433 ± 0.009 GeV [9].

To cross-check our results, we use the $Z \rightarrow ee$ distribution from real ATLAS data and find the half-maximum fit from the electron p_T distribution. The Z^0 boson is used as the mass of the Z^0 boson is well known to a high accuracy. The procedure is identical with the W boson except with replacing the dataset `Wenu to Zee`. We obtained the half-maximum $h = 48.457 \pm 0.045$ GeV, shown in Fig. 6.4.4. From this, we obtain the mass of the Z^0 boson as such:

$$m_Z = 90.94 \pm 0.20 \text{ GeV} \quad (6.4.8)$$

which is 1.26σ from the literature value of the Z^0 boson mass of 91.1876 ± 0.0021 GeV. Thus the obtained Z^0 boson mass is not within one sigma of the literature value. This may be attributed to the noisy dataset. We observe from Fig. 6.4.4 that the peak in the ATLAS data has large fluctuations thus decreasing the goodness of fit for the half-maximum.

6.5 Systematic Errors

As mentioned in the previous section, the error calculation for the W boson mass was purely statistical. Thus we need to determine the systematic uncertainties associated with the measurement.

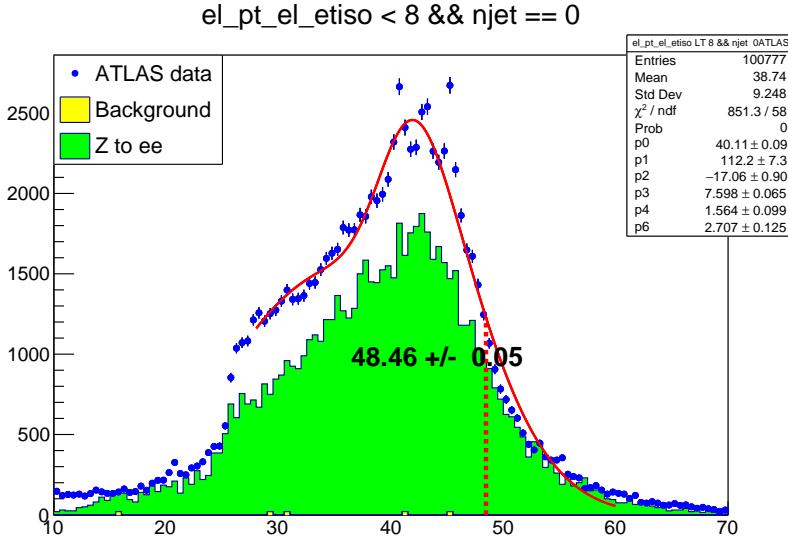

Figure 6.4.4: Same as Fig. 6.4.1 but for real ATLAS data for the $Z \rightarrow ee$ candidate events.

6.5.1 Calibration

The first systematic uncertainty we need to consider is from the calibration of the electrons as our calibration is inexact. To quantitatively determine the systematic error, we use the Z^0 boson mass we have obtained from our cross-check calculations. As the measurement of the W boson mass contains other systematic errors, we can neglect such errors by observing the relative uncertainty between the systematic error in the Z^0 boson and W boson mass:

$$\frac{\sigma_{m_Z,\text{calib}}}{m_Z} = \frac{\sigma_{m_W,\text{calib}}}{m_W} \implies \sigma_{m_W,\text{calib}} = m_W \frac{\sigma_{m_Z,\text{calib}}}{m_Z} \quad (6.5.1)$$

As we have performed our calibration using the Z^0 boson mass, we can determine the systematic error from calibration in this manner. The systematic error from calibration for the Z^0 boson is given by the difference from the obtained and expected value: $\sigma_{m_Z,\text{calib}} = 90.94 - 91.1876 = -0.25 \text{ GeV}$ (where we have taken two significant figures to match those of the statistical errors). From this, we obtain the systematic error from calibration for the W boson mass as such:

$$\sigma_{m_W,\text{calib}} = (80.45 \text{ GeV}) \cdot \left(\frac{-0.25 \text{ GeV}}{90.94 \text{ GeV}} \right) = -0.22 \text{ GeV} \quad (6.5.2)$$

Here, we keep the significant digits to two decimal places to match those of the statistical errors. We observe that the error from the calibration plays a significant impact for the value of the two masses, as they are both larger than the statistical error.

6.5.2 QCD Background Scale Factor

The second systematic uncertainty we need to consider is from the QCD background scale factor. In order to determine this, we modify the scale factors until the deviation in the shape of the high QCD background region in the `el_etiso` distribution ($\text{el_etiso} < 10 \text{ GeV}$) between the real and simulated data is significant. We then took the maximal and minimal scale factors that yield this deviation and determine the W boson mass with the same configuration.

The QCD scale factors, as mentioned in Sec. 6.3 were chosen to be 0.28 and 0.32 for the minimal and maximal scale factor respectively. Table 6.3 shows the W and Z^0 boson masses obtained from using the two scale factors. The half-maxima fits obtained for each scale factor for the simulated W boson mass for $m_W = 80 \text{ GeV}$ is shown in Appendix A. [edit appendix referencing for each figure \(and code\)!](#)

To obtain the systematic uncertainty, we subtracted the masses from the maximal / minimal scale

QCD Scale Factor	m_W/GeV	m_Z/GeV
0.28	$80.420 \pm 0.104 \text{ GeV}$	$90.92 \pm 0.20 \text{ GeV}$
0.32	$80.470 \pm 0.103 \text{ GeV}$	$90.92 \pm 0.18 \text{ GeV}$

Table 6.3: W boson and Z^0 boson masses from QCD scale factors of 0.28 and 0.32. The variation of the QCD scale factor does not show large deviation between the real and simulated data between these values.

Fit Region	m_W/GeV	m_Z/GeV
[26, 65]	$80.35 \pm 0.11 \text{ GeV}$	$90.74 \pm 0.23 \text{ GeV}$
[30, 50]	$80.63 \pm 0.12 \text{ GeV}$	$90.46 \pm 0.25 \text{ GeV}$

Table 6.4: Same as Table 6.3 but for maximal and minimal region widths in which the distribution does not significantly deviate from the initial one (shown in Fig. 6.4.1).

factor from our scale factor we have set (0.30), yielding:

$$\sigma_{m_W, \text{QCD}, \text{max}} = 80.47 \text{ GeV} - 80.45 \text{ GeV} = 0.02 \text{ GeV} \quad (6.5.3)$$

$$\sigma_{m_W, \text{QCD}, \text{min}} = 80.42 \text{ GeV} - 80.45 \text{ GeV} = -0.03 \text{ GeV} \quad (6.5.4)$$

$$\sigma_{m_Z, \text{QCD}} = 90.94 \text{ GeV} - 90.92 \text{ GeV} = 0.02 \text{ GeV} \quad (6.5.5)$$

$$(6.5.6)$$

where the systematic error for the Z^0 boson was determined by subtracting the mass of either scale factor (0.28, 0.32) from our original case (0.30) as both scale factors yield the same value of m_Z . As the systematic error is small, it is clear that the QCD background scale factor does not impact the analysis when compared to the other systematic errors and the statistical error.

6.5.3 Fit Region

The third systematic error that we need to consider is the impact of the fit region as the choice of the fitting region strongly impacts the half-maximum chosen for each distribution. To quantify this, we take the maximal and minimal region width of the fitting range such that the shape of the fit stays consistent with the original distribution from Fig. 6.4.1. Table 6.4 shows the obtained W and Z^0 boson masses obtained at these ranges. The half-maximum plot with $m_W = 80 \text{ GeV}$ are shown in Appendix A.

The systematic error is evaluated similarly to how the systematic error was evaluated for the QCD scale factor, resulting in:

$$\sigma_{m_W, \text{region}, \text{max}} = 80.35 \text{ GeV} - 80.45 \text{ GeV} = -0.10 \text{ GeV} \quad (6.5.7)$$

$$\sigma_{m_W, \text{region}, \text{min}} = 80.63 \text{ GeV} - 80.45 \text{ GeV} = 0.18 \text{ GeV} \quad (6.5.8)$$

$$\sigma_{m_Z, \text{region}} = 90.46 \text{ GeV} - 90.92 \text{ GeV} = -0.46 \text{ GeV} \quad (6.5.9)$$

$$(6.5.10)$$

where the systematic error of the Z^0 boson was set as such since the difference of the Z^0 boson mass between the maximal region and the original region is smaller than those from the minimal and original region. Thus we observe that the impact from varying the fit region is much larger than those from the QCD scale factor. This impact is further observed for the Z^0 boson and this systematic error is in fact larger than the statistical error. This implies that the deviation from the literature value is more influenced by the choice of the fit region rather than the statistical uncertainty in the dataset.

6.5.4 Cut Selections

Finally, we investigate the effect of the cuts we applied to the obtained masses of the W and Z^0 boson. In order to quantify this, we obtain the W and Z^0 boson masses for each cut that we apply. Table 6.5 shows the resulting masses. See Appendix A for the half-maximum plot for simulated mass with $m_W = 80 \text{ GeV}$.

From this, we observe that selecting `njet == 0` reduces the masses of the W and Z^0 boson. This is caused by the reduced transverse momentum of the W and Z^0 boson which in turn reduces the smearing

Cut Selection	m_W/GeV	m_Z/GeV
None	$81.680 \pm 0.125 \text{ GeV}$	$96.21 \pm 0.52 \text{ GeV}$
<code>njet == 0</code>	$80.28 \pm 0.10 \text{ GeV}$	$90.91 \pm 0.17 \text{ GeV}$
<code>el_etiso < 8</code>	$80.97 \pm 0.14 \text{ GeV}$	$93.50 \pm 0.72 \text{ GeV}$
<code>el_etiso < 8 & njet == 0</code>	$80.45 \pm 0.10 \text{ GeV}$	$90.94 \pm 0.20 \text{ GeV}$

Table 6.5: Same as Table 6.3 but for the different cuts applied. The last entry show the results from the cuts that we chose for our analysis.

in the Jacobi peak. Further the cut selection `el_etiso < 8` increases the mass of the particle, which is attributed by identification of more isolated electrons in the jets. We thus observe that applying both cuts (as we do in our analysis) reduces the masses, but not as much as applying a single cut for the number of jets.

6.5.5 Result

Thus by including both systematic and statistical uncertainties, we obtain the mass of the W boson as follows:

$$m_W = 80.45 \pm 0.10(\text{stat.}) - 0.22^{+0.02}_{-0.03} {}^{+0.10}_{-0.18} (\text{sys.}) \text{ GeV} \quad (6.5.11)$$

and the mass of the Z^0 boson is given as such:

$$m_Z = 90.94 \pm 0.20(\text{stat.}) - 0.25 + 0.02 - 0.46 (\text{sys.}) \text{ GeV} \quad (6.5.12)$$

We observe that taking into account both systematic and statistical uncertainties, the W and Z^0 boson mass are both within one sigma of the most recent value 80.433 ± 0.009 GeV and literature value 91.1876 ± 0.0021 GeV respectively.

Chapter 7

Conclusion

In this report, we analyzed the real and simulated data obtained from the ATLAS detector located in the Large Hadron Collider in Geneva, Switzerland. From this, we obtained the mass of the W boson after performing calibration to our dataset.

We first explored the graphical interface **ATLANTIS** that allows us to observe the signatures from different particle production from proton-proton collisions. We investigated the signatures shown by simulated datasets for the electron, muon, photon, tau lepton, dijets, W and Z^0 boson. From this, we observed that the signatures match the expected behavior from their particle properties. We then explored two other datasets. In the mystery data set, we start from the vertex and work our way outwards. After going through each layer of the detector and looking at the possible SM processes responsible for the hits or energy deposit, we do not rule out any SM process that is not contained in the data set. We also observed the real ATLAS dataset that detected cosmic ray muons in the detector. We observed that the muon angular distribution does not yield the $\cos^2\theta$ behaviour as observed in sea level, but rather a sharper distribution instead.

We then performed calibration to our dataset using the Z^0 boson mass with the invariant m_{ee} distribution. For the uncalibrated data, the mass was 89.87 ± 0.02 GeV and the resolution was 2.588 ± 0.026 . After applying energy scaling in the following order for variables in different regions of its spectrum: phi, eta, mindrjet, etiso and pt, one after the other, we were able to achieve a mass of 91.198 ± 0.0196 GeV and a resolution of 2.342 ± 0.024 .

From this calibration, we measured the mass of the W boson. We first verified that the calibration was applied correctly by comparing the invariant m_{ee} distribution, yielding the Z^0 boson mass of 91.17 ± 0.01 GeV, which is within one sigma to the literature value of 91.1876 ± 0.0021 GeV. The mass of the W boson was measured by using the Jacobi peak from the electron p_T distribution. We first investigated different kinematical parameters that affect the distribution. We observed that the number of jets `njet` increases the transverse momentum of the W boson, which ideally should be zero. Thus we applied a cut so that `njet == 0` in our analysis.

We then set the QCD scale factor, which controls the amount of QCD background in the simulated dataset, such that its amplitude reaches those from the real ATLAS data. For this, we observed the high QCD background region of the `e1_etiso` distribution (`e1_etiso > 10 GeV`), and chose a value such that the amplitudes between real and simulated data match. This was set to be 0.3 for our dataset. Furthermore, we applied a cut so that we are in the low QCD background regime, i.e. `e1_etiso > 8 GeV`.

We then determined the half-maximum fit of the Jacobi peak for seven simulated datasets, each with different W boson masses. The half-maximum were then used to obtain a linear fit between the known W boson masses and the half-maxima. From this, we obtained the slope and intercept to be $a = 0.5214 \pm 0.0080$ and $b = 1.04 \pm 0.64$ GeV respectively. This was then used to determine the mass of the W boson using the half-maximum obtained from the real ATLAS data. From this, we obtained $m_W = 80.45 \pm 0.10$ GeV, which agrees with the most recent value of 80.433 ± 0.009 GeV within one sigma.

To cross check our analysis, we determined the mass of the Z^0 boson using the same procedure as before, obtaining $m_Z = 90.94 \pm 0.20$ GeV, which was 1.26σ away from the literature value. The deviation was attributed to the noisy dataset, where the noise is particularly prominent at the peak.

Finally, we considered the different systematic effects that could influence our measurement. The calibration process and the variation of the fit region influenced the W boson mass significantly as it yielded uncertainties that are close to or larger than the statistical uncertainty. The effect on the QCD

scale factor, however, was minimal as it yielded at maximal uncertainty value of 0.03GeV. The different cut selections applied also strongly affected our measurement as it reduced the value of the W boson mass.

All in all, from this experiment we obtained the W boson mass to be $m_W = 80.45 \pm 0.10(\text{stat.}) - 0.22^{+0.02}_{-0.03}{}^{+0.10}_{-0.18}(\text{sys.})\text{GeV}$, which was within one sigma of the most recent value of 80.433 ± 0.009 GeV. The Z^0 boson mass, after considering the systematic effects, was also shown to be $m_Z = 90.94 \pm 0.20(\text{stat.}) - 0.25 + 0.02 - 0.46(\text{sys.})\text{GeV}$, which is now within one sigma of the literature value 91.1876 ± 0.0021 GeV.

Additional Figures

Here we present additional figures of interest.

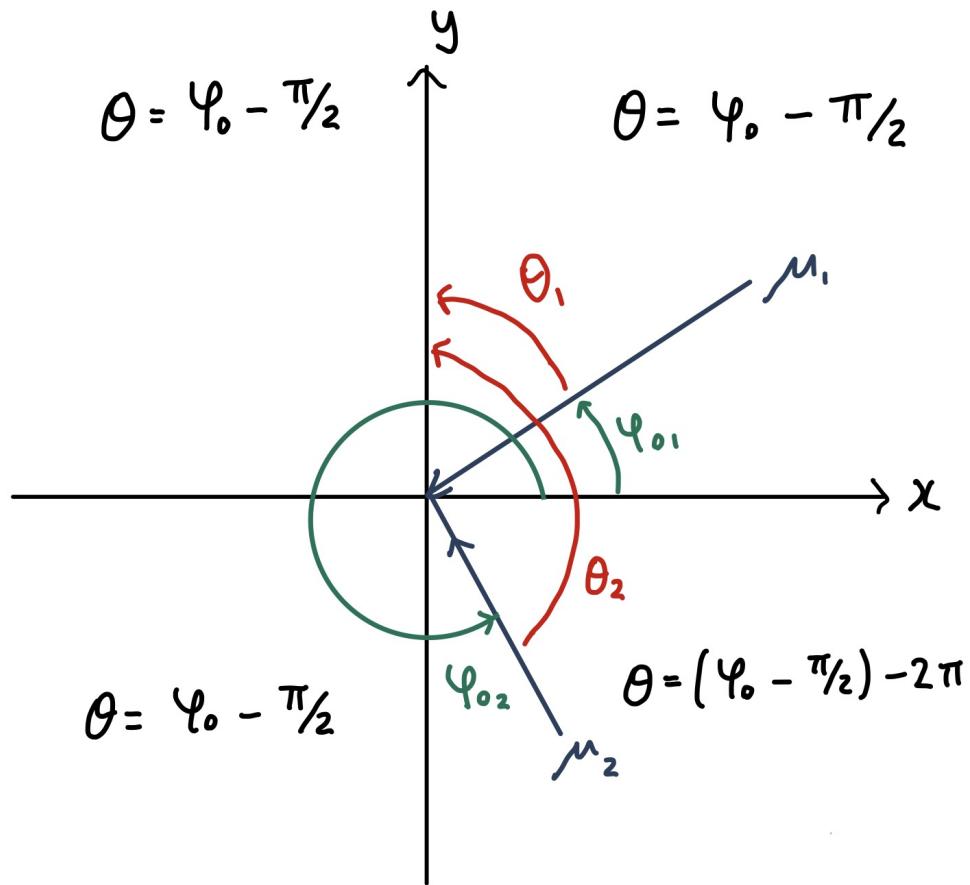

Figure A.0.1: Transformation from azimuthal angle ϕ_0 to angle from local zenith θ performed in the analysis of cosmic ray muons in Assignment 8 of Chap. 4. The zenith angle in the 4th quadrant (θ_2) transforms differently from angles in all other quadrants (ex. 1st quadrant, θ_1) due to how the domain of ϕ_0 is defined.

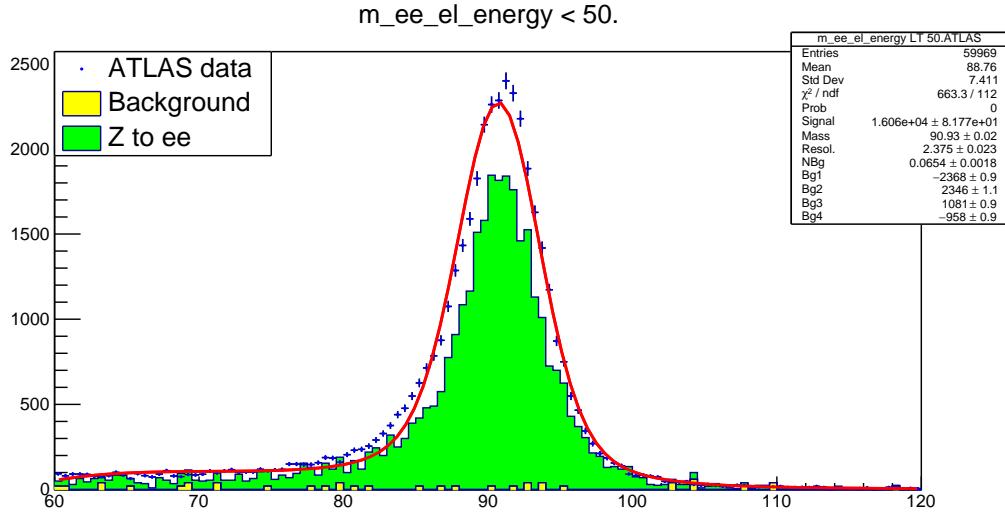

Figure A.0.2: The invariant mass distribution of ee from $Z \rightarrow ee$ decays with $E_e < 50$ GeV. The blue points are the real data from ATLAS, the red line is the Voight function fit, and the green histogram is the simulated data. The background is also shown in yellow.

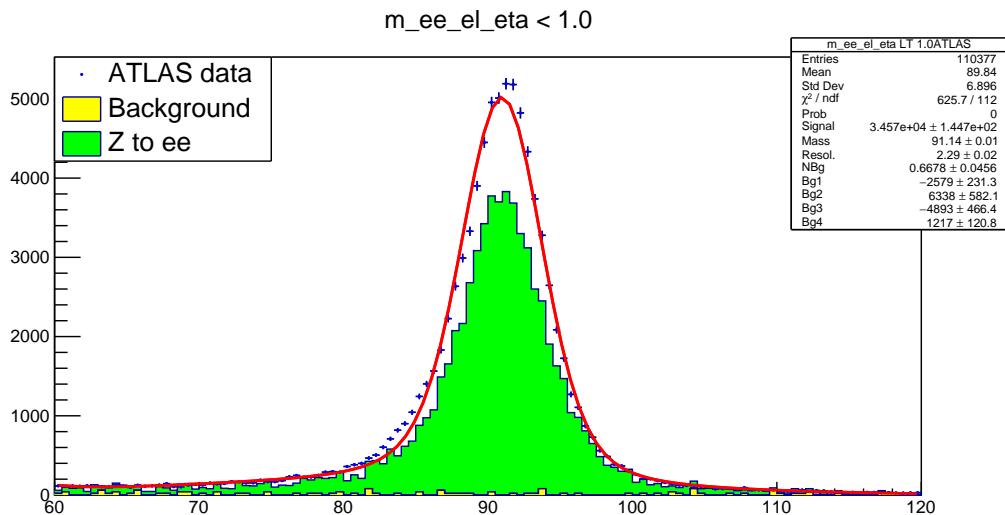

Figure A.0.3: Same as Fig. A.0.2 but for cuts with $\eta < 1$.

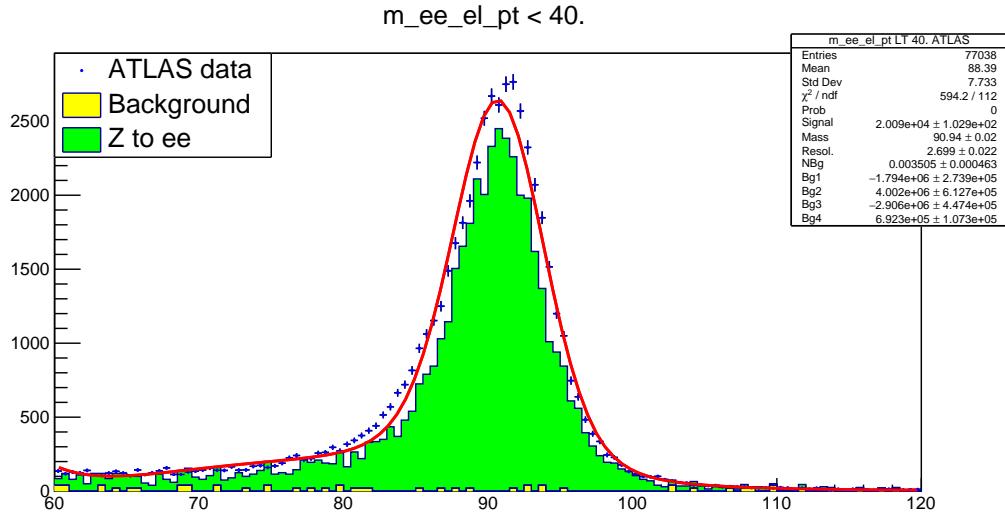

Figure A.0.4: Same as Fig. A.0.2 but for cuts with $p_{T_e} < 40$ GeV.

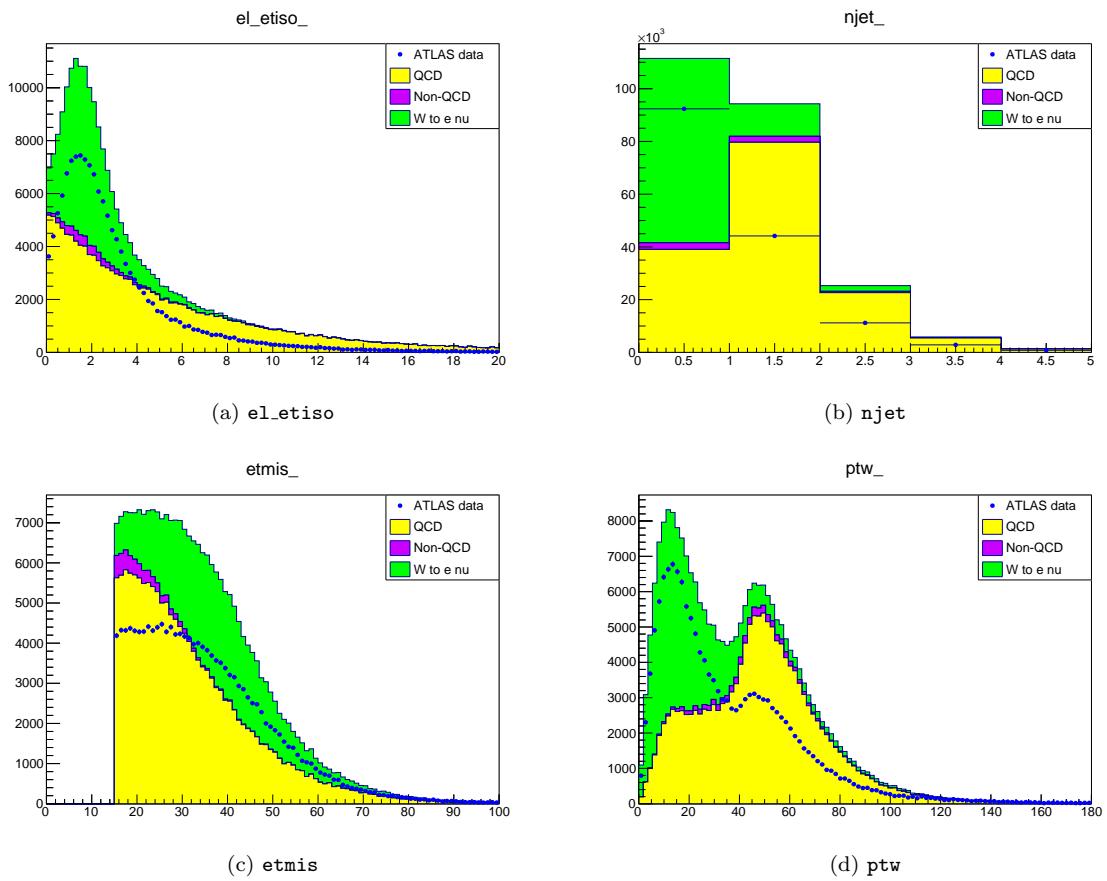

Figure A.0.5: Same as Fig. 6.2.1 but for other parameters of interest.

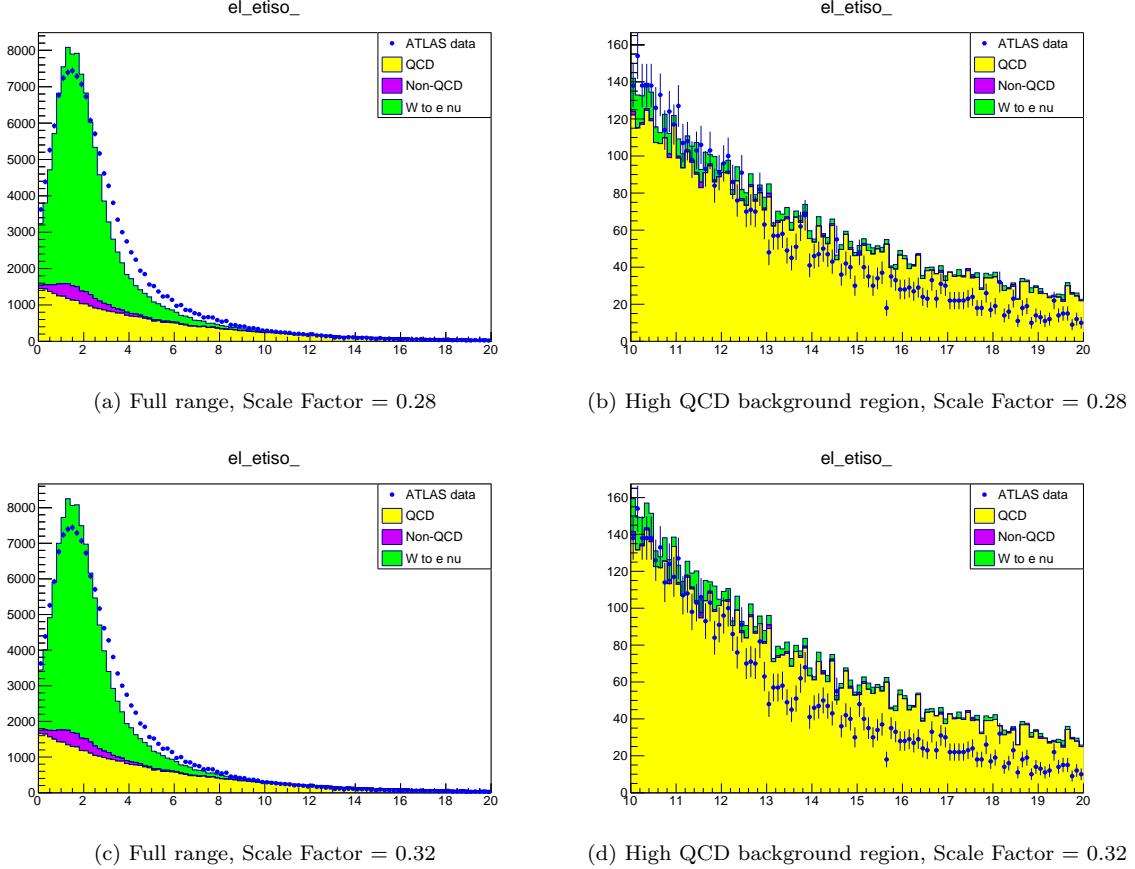

Figure A.0.6: el_etiso distribution for the whole distribution (left) and in the region with high QCD background (right) for QCD scale factors of 0.28 (top) and 0.32 (bottom).

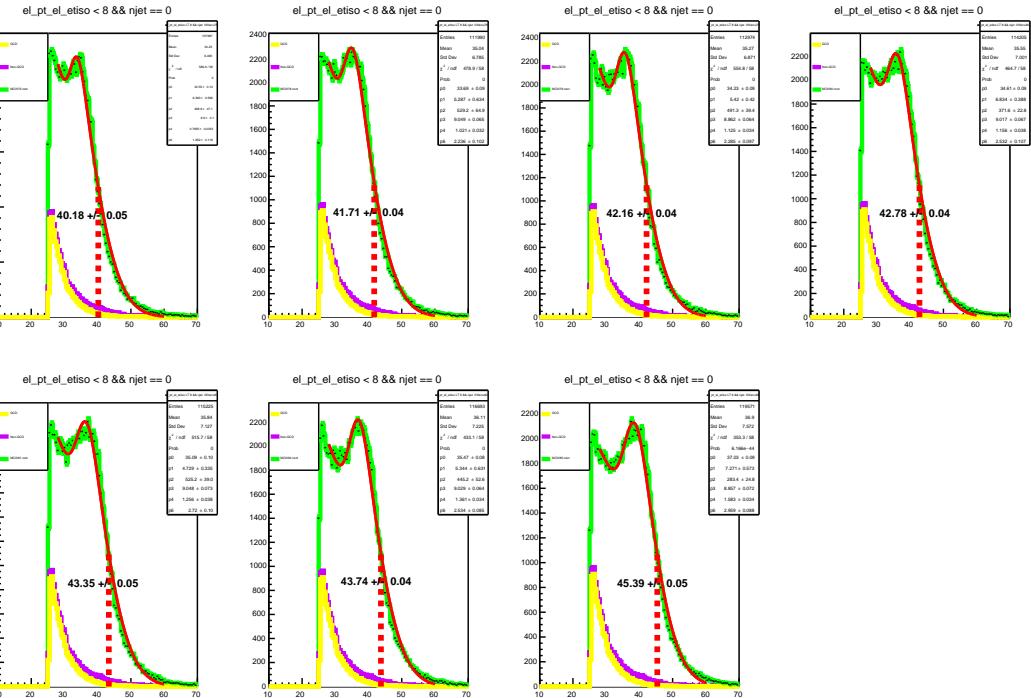

Figure A.0.7: Half-maximum fit of the electron p_T spectrum for different values of the W boson mass.

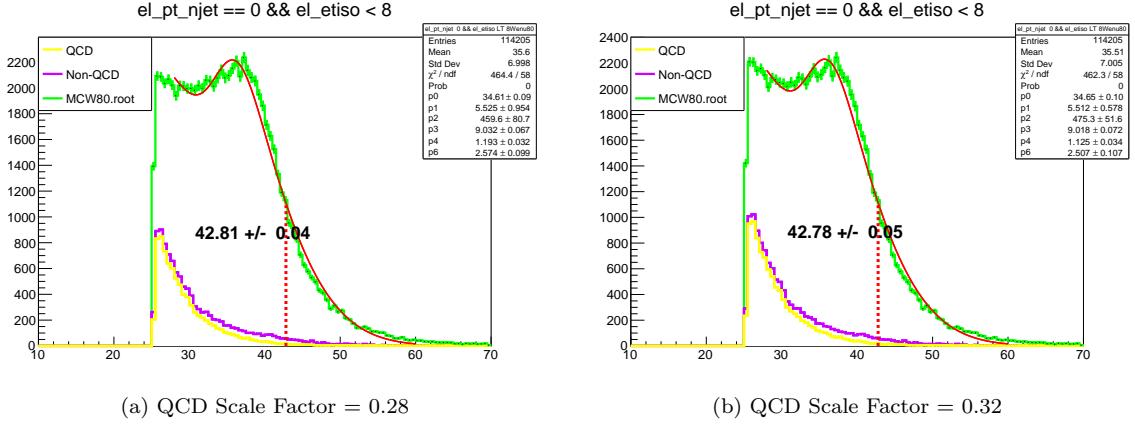

Figure A.0.8: The half-maximum fits for QCD scale factors of 0.28 and 0.32. This is used for determining the systematic effects of the W boson mass.

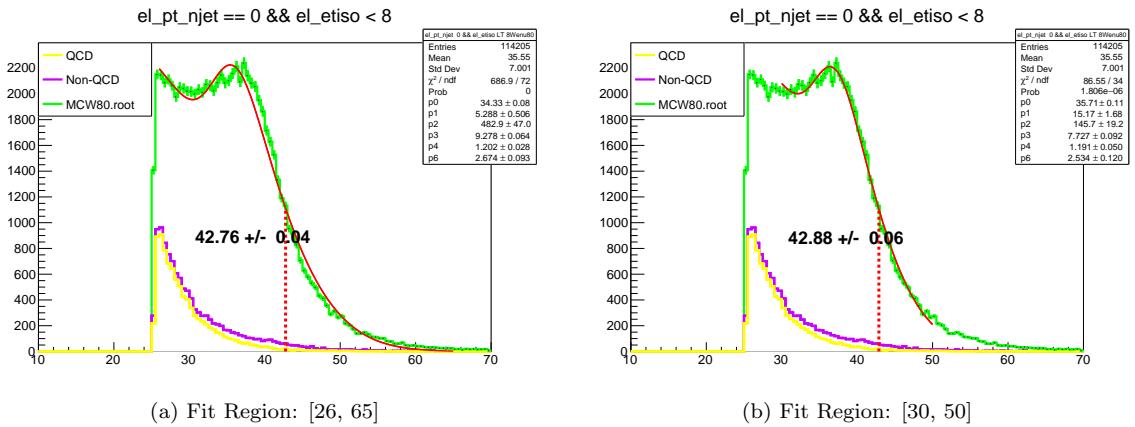

Figure A.0.9: Same as Fig. A.0.8 but for the fit regions [26, 65] and [30,50] GeV instead. This is used to determine the systematic effects of the variation of the fit region to the W boson mass.

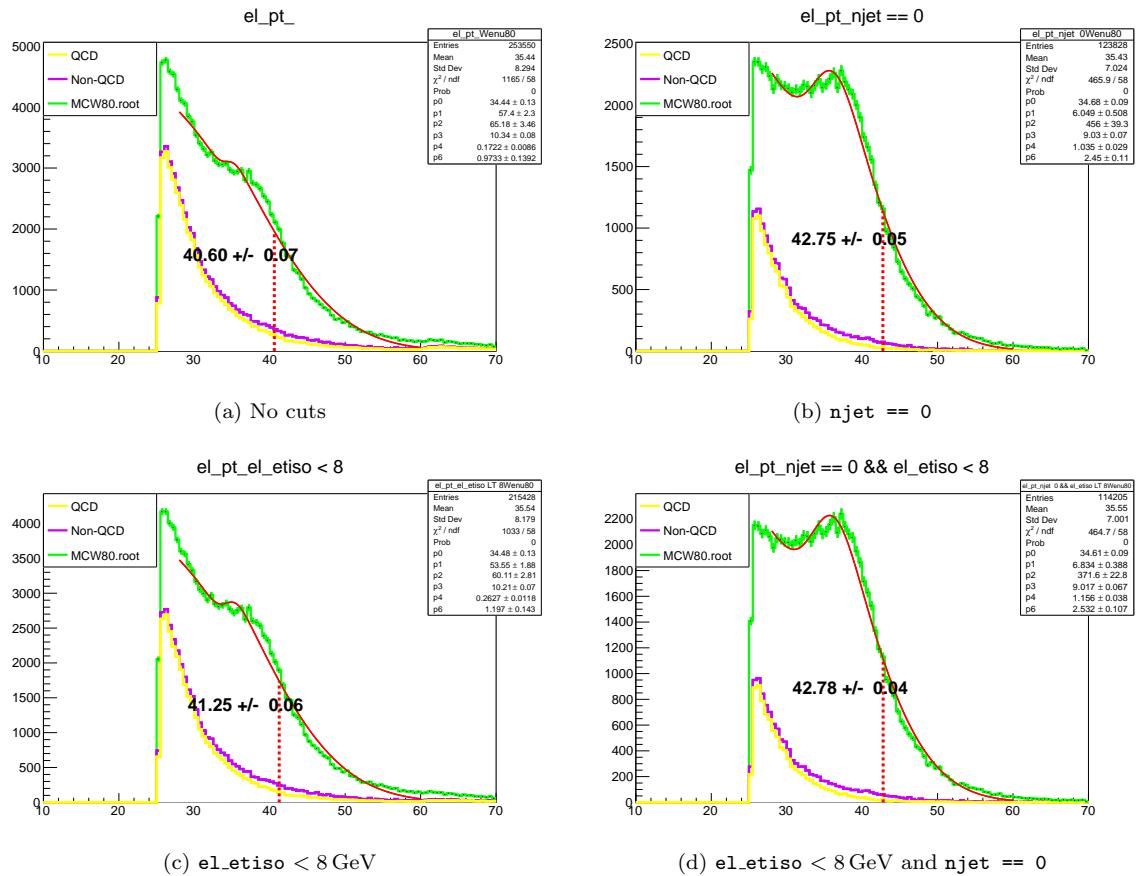

Figure A.0.10: Same as Fig. A.0.8 but for different cut selections: (a) no cuts, (b) with no jets, (c) with $el_{\text{etiso}} < 8 \text{ GeV}$, and (d) with both cuts applied.

Appendix B

Code

The code for the final ElecCalib.C file is shown below.

```
double ElecCalib(double e_raw, double pt, double eta,
    double phi, double etiso, double eoverp, double mindrjet)
{
    double dummy=pt*eta*phi*etiso*eoverp*mindrjet;
    double energy = e_raw;

    // final fit parameters and taking the mass of Z as 91.18

    // phi cuts
    if(fabs(phi)>0. && fabs(phi)<0.4) energy = energy * 91.18/89.69;
